KEYWORDS: TRIGEMINAL GANGLION NEURONS / WHOLE CELL PATCH-CLAMP RECORDING / ASICS / CGRP / SMALL- TO MEDIUM-SIZED NEURONS / LARGE-SIZED NEURONS / EXCITABILITY

UGGRIT JUNSRE: THE EFFECT OF CALCITONIN GENE-RELATED PEPTIDE ON ACID-SENSING ION CHANNEL ACTIVITY IN PRIMARY CELL CULTURE OF TRIGEMINAL GANGLION NEURONS. ADVISOR: PROF.ANAN SRIKIATKHACHORN, M.D., CO-ADVISOR: ASSOC. PROF.SAKNAN BONGSEBANDHU-PHUBHAKDI, Ph.D., 87 pp.

The local tissue acidosis of inflammatory events leads to physiological pH drop and causes headache via the activation of small-to-medium-sized trigeminal ganglion (TG) neurons. Acid sensing ion channels (ASICs) are the acidic sensor in which requiring at least pH 7.0 to cause neurotransmitter release, such as CGRP. CGRP elevates nociceptive signal by activating its receptor on large-sized neurons. However, the role of CGRP on ASICs activity has not been investigated. Moreover, the role of pH 7.0 on TG neurons has still unclear. The present study aimed to investigate the effect of pH 7.0 on ASICs and to investigate whether the effect of CGRP can modulate ASICs activity in both the small-to-medium-sized and large-sized neurons. Primary-culture TG neurons were performed by whole-cell patch clamp recording that injected depolarizing current steps in long and short periods. The electrophysiological properties of neurons were compared between physiological pH and pH 7.0 in both with and without CGRP. After lowering pH, pH 7.0 increased the excitability in the small-to-medium-sized neurons while pH 7.0 cannot modulate the excitability in the large-sized neurons. Moreover, CGRP can directly increase the excitability in the large-sized neurons by activating its receptor. However, CGRP would modulate the excitability in the small-to-medium-sized neurons via the activation of satellite glia cells with unknown mechanism, but would possibly be the signaling cascade pathways. These finding indicate that pH 7.0 can modulate the excitability of small-to-medium-sized neurons and CGRP can directly modulate the excitability of large-sized neurons resulting in the increase of pain perception. However, the effect of CGRP to modulate the excitability in pH 7.0 should be further investigated.

ACKNOWLEDGEMENTS

I would like to express my sincere gratitude to my thesis advisor, Professor Anan Srikiatkachorn for his valuable mentor and supervision which have guided me to work and succeed my research. I would like to express my sincere appreciation to my thesis co-advisor, Associated Professor Dr. Saknan Bongsebandhu-phubhakdi for his mentor, evaluation, suggestion, and support on this research.

I would like to express my gratefulness to Assistant Professor Dr. Nipan Israsena, for his advice and helpful cell culture practice. I appreciated to give my thankful for Mr. Chatikorn Boonkrai for his devoting teach-in cell culture. I would like to give my thankfulness to Dr. Montree Maneepark for his suggestion and mentor in my preparation in the experiment. I also would like to express my sincere gratitude to Assistant Professor Dr. Robin James Storer, for his book, suggestion, idea on my preparation in thesis writing.

Finally, I would like to thank the funding agencies for their financial support of this research. The research was supported by the Neuroscience of Headache Research Unit, “Intergrated Innovation Academic Centre: IIAC”: 2012 Chulalongkorn University Centenary Academic Development Project, National Research University Project, Office of Higher Education Commission (WCU-008-HR-57), Government Research Budget 2014 and Ratchadapiseksompoj Fund from the Faculty of Medicine, Chulalongkorn University.

ATP	adenosine triphosphate
BBB	blood brain-barrier
BK	bradykinin
BK _{Ca}	big conductance calcium-activated potassium channel
C	cervical
CaMKII	calcium/calmodulin-dependent protein kinase II
cAMP	cyclic adenosine monophosphate
CGRP	calcitonin gene-related peptide
CLR	calcitonin-like receptor
CNS	central nervous system
CREB	cAMP response element binding protein
CSD	cortical spreading depression
D	domain
DAG	diacylglycerol

ddH ₂ O	double distilled water
DRASIC	dorsal root acis-sensing ion channel
DRG	dorsal root ganglion
E _m	membrane potential
ENS	enteric nervous system
ER	endoplasmic reticulum
FMRF	phenylalanine-methionine-arginine-phenylalanine
FT	falling time
GTP	Guanine triphosphate
HBSS	hank's balanced salt solution
HP	holding potential
IL	interleukine
IFM	isoleucine, phenylalanine, and methionine
IP ₃	inositol 1,4,5-trisphosphate
K2P	two pore domain potassium channel
K _v	voltage-gated potassium channel
MAPK	mitogen-activated protein kinase
MMP-9	matrix metalloproteinases 9
ms	millisecond
mV	millivolt
Na _v	voltage-gated sodium channel

NPFF	neuropeptide phenylalanine -leucine-phenylalanine-glutamine-proline- glutamine-arginine- phenylalanine
NPSF	neuropeptide serine-leucine-alanine-alanine-proline-glutamine-arginine- phenylalanine
NGF	nerve growth factor
NO	nitric oxide
NS	nociceptive specific
P2X ₃	purinergic receptor P2X, ligand-gated ion channel 3
PDL	poly-D-lysine
PM	pore module
PGE ₂	prostaglandin E2
PKA	protein kinase A
PKC	protein kinase C
PIP ₂	phosphatidylinositol 4,5-biphosphate
PLC	phospholipase C
PNS	peripheral nervous system
RAMP1	receptor activity-modifying proteins 1
RCP	receptor component protein
RT	rising time
S	segment
SEM	standard error mean

SGC	satellite glia cell
SK _{ca}	small conductance calcium-activated potassium channel
SP	substance P
SPASIC	spinal cord acid-sensing ion channel
SNAP-25	synaptosomal-associated protein of 25 kDa
TWIK	two pore domain potassium channel
TASK-3	TWIK-related acid sensitive K ⁺ channel 3
TCC	trigemino-cervical complex
TG	trigeminal ganglion
TNC	trigeminal nucleus caudalis
TNF	tumor necrosis factor
TRESK	TWIK-related spinal cord K ⁺ channel
TRPV1	transient receptor potential vanilloid 1
VPM	ventromedial thalamic nucleus
VSD	voltage sensing domain
WDR	wide dynamic range

CHAPTER I

INTRODUCTION

Background and Rationale

The inflammatory events of trigeminal ganglion (TG) neurons associated with headache leading to an acidosis of local area is called 'local tissue acidosis' (1, 2). The levels of pH in the local tissue acidosis are decreased from physiological pH to pH 5.4 that can activate the specific receptors and nociceptors to produce headache (3, 4). These receptors are defined as acid-sensing ion channels (ASICs) and transient receptor potential vanilloid type 1 (TRPV1) that responds to pH in different ranges. ASICs activation requires pH change from 7.4 to 7.0, while TRPV1 activation requires the pH change less than 6.0. (5, 6). Thus, ASICs are the primary pH sensor in response to acidic noxious stimulus.

ASICs are the voltage-independent ligand-gated cation channels that assemble three subunits to form function. ASICs are activated by the extracellular proton (H^+), and then this activation results in permeability to sodium (Na^+) ions (7). ASICs are divided into ASIC1a, ASIC1b, ASIC2a, ASIC2b, ASIC3, and ASIC4 that distribute in many tissues in the central and peripheral nervous system (CNS and PNS) (8). In TG and dorsal root ganglion (DRG), ASIC1a and 3 distribute on small-to-medium-sized neurons, while ASIC3 distributes on large-sized neurons (9-11). Although small-to-medium-sized neurons implicate with nociceptor, large-sized neurons implicates on mechanoreceptor and proprioceptor (8, 12). In the range of pH, pH change from 7.4 to 7.0 sufficiently activates ASICs on the small-to-medium-sized neurons that can produce the excitability in DRG, nodose ganglion, and dural afferent part of TG (13-15). However, the physiological mechanism that pH 7.0 can increase the excitability in TG neurons is still unclear. Especially, the effect of pH 7.0 on the small-to-medium-sized and large-sized neurons should be investigated because the expression patterns of ASICs on them are difference.

ASICs co-express with other receptors, such as TRPV1, purinergic receptor (P2X), purinoceptor ligand-gated ion channel 3 (P2X₃). Moreover, ASICs co-express

with calcitonin gene-related peptide (CGRP) in the small- to-medium-sized neurons. The co-expression of ASICs and CGRP is thought to be the reason that makes TG neurons respond to low pH, capsaicin, and ATP stimuli (16-18). CGRP activation can sensitize P2X₃ that leads to prolonged headache, and CGRP can also up-regulate TRPV1 expression (19, 20). The modulation of CGRP on ASICs is unknown, albeit the activation of ASICs can modulate the release of CGRP from the small-to-medium-sized neurons (21).

CGRP, a 37 amino acid vasodilatory neuropeptide, is released from the small-to-medium-sized neurons. CGRP acts through the functional CGRP receptor to dilate vessel, activate mast cells and satellite glia cells (SGCs), and modulate the large-sized neurons (22). Mast cells activation leads to degranulation and release of the inflammatory mediators, and SGCs activation leads to release of the pro-inflammatory mediators (23). These mediators can activate, in turn, the small-to-medium-sized neurons (24). The implication between CGRP and ASICs was studied by the observation of co-expression. Both ASICs and CGRP are co-expressed in small-to-medium-sized neurons in DRG and TG (10, 11). When the extracellular proton activates ASICs on TG neurons, Na⁺ influx occurs that results in the increase of intracellular Na⁺. Then, the elevation of intracellular Na⁺ promotes the release of CGRP (21). However, there is co-expression of CGRP and ASICs3 in large-sized TG neurons (10, 25). Thus, whether CGRP can modulate ASICs via its receptor should be investigated.

Research questions

How does low pH (pH 7.0) modulate the neuronal excitability of the small-to-medium-sized neurons? Does pH 7.0 have any effect on ASICs of the large-sized neurons? Does CGRP have any effect on ASICs activity of the small-to-medium-sized and large-sized neurons?

Objectives

1. To determine the effect of pH 7.0 on ASICs in the small-to-medium-sized neuron.
2. To investigate the effect of pH 7.0 on ASICs in the large-sized neurons.
3. To investigate the modulation of CGRP on ASICs activity in the small-to-medium-sized neurons.
4. To investigate the modulation of CGRP on ASICs activity in the large-sized neurons.

Hypothesis

ASICs activation increases the neuronal excitability in the small-to-medium-sized neurons, while CGRP modulation enhances the AP induction in the large-sized neurons.

CHAPTER II

LITERATURE REVIEWS

Trigeminal nociceptive system

Head and face are innervated by the trigeminal nerve, which is divided into three branches; ophthalmic (V1), maxillary (V2), and mandibular (V3) branches (26). First, the ophthalmic branch (V1) innervates frontal sinus, orbit and eye, tentorium cerebelli, anterior and middle cerebral arteries, and superior sagittal sinus. Second, the maxillary branch (V2) innervates upper jaw, nose, and maxillary sinus. Third, the mandibular branch (V3) innervates lower jaw, masticatory muscles, and temporomandibular joint (27). Moreover, three branches also give the fibers to supply dura mater of brain structures including dural and pial vessels (28). These branches emerge from their neurons in the trigeminal ganglion (TG) and continue to the brainstem and upper cervical levels.

Trigeminal ganglion neurons

TG neurons, the first-order neuron, are pseudounipolar and enveloped in satellite glia cells at their cell bodies (29, 30). On the basis of the morphological and histological differences, the body of the TG neurons are classified into large light neurons, medium light neurons, medium dark neurons, small light neurons, and small dark neurons (29, 31). However, the TG neurons are divided into small-sized ($> 30 \mu\text{m}$ or $> 600 \mu\text{m}^2$), medium-sized ($30\text{-}40 \mu\text{m}$ or $1200 \mu\text{m}^2$), and large-sized ($< 40 \mu\text{m}$ or $< 1200 \mu\text{m}^2$) neurons by using the immunohistologically neurochemical markers, including calcitonin gene-related peptide (CGRP) and phosphorylated neurofilament heavy chain 200 kDa (NF200). Each size of neurons has unique fiber; the small-sized and medium-sized neurons are defined as a nociceptive phenotype, give the unmyelinated C-fiber and thinly myelinated A-delta fiber, respectively. Thought, the large-sized neuron is defined as a non-nociceptive phenotype, gives the thick myelinated A-beta fiber (17, 32, 33). The A-beta fibers respond to the innocuous touch and proprioception stimuli, while the A-delta fibers detect and C-fibers detect

the noxious heat mechanical, thermal, and chemical stimuli (34). Following the basis of the protein expression, the nociceptive phenotype neurons are sub-classified into the peptidergic which expresses CGRP and substance P, and non-peptidergic which expresses Ret protein and binding isolectin B₄ (12, 35). However, both the peptidergic and non-peptidergic subtypes can overlap between the co-localization of CGRP and IB₄ in the rat (36). Moreover, the TG neurons contain neuropeptide that concerning with size of neurons; small sized neurons contain substance P, CGRP, cholecystokinin, somatostatin, vasoactive intestinal polypeptide, and gelatinin; medium size neurons contain CGRP and neuropeptide Y; and large-sized neurons contain cholecystokinin and neuropeptide Y (33).

Thus, phenotypes of TG neurons convey the non-nociceptive and nociceptive information from peripheral stimuli to central nervous system for interpreting the input information into pain perception.

Nociceptor and pain perception

Pain is an unpleasant perception and emotion through an interaction between mechanisms of a sensory and cognition, which in the midst of the inflammation, disease, or trauma. The results of pain lead to a suffering and an avoidance from threatening situations (37, 38). Threat or stimulus, which potentially damages the tissues is defined as 'noxious'. For example, the heat that elicits pain in animals and human is higher than 45 °C, and is defined as noxious heat stimulus. Moreover, noxious can also be mechanical and chemical stimuli. These noxious stimuli have receptors with high-threshold for activation, and called 'nociceptor' or 'nociception', which were defined by Charles Sherrington (1906). Primary trigeminal nociceptors including dorsal root ganglion (DRG) and trigeminal ganglion (TG) neurons send unmyelinated C-fibers and thinly myelinated A-delta fibers, specifically mediate pain via responding in the single of noxious stimulus or the several of noxious stimuli, in which defining as polymodal nociceptors (34, 39). The nociceptors has three functional roles that transduce peripheral terminal, and convert external stimuli into electrical impulses including action potential (AP), conduction of impulses (or AP)

that run along axon to cell body, transmission of central terminal that synapses on specific nociceptive second order neurons in the central nervous system (CNS) (40). Moreover, the nociceptors also enable the sensitization by threshold reduction and response elevation to the noxious stimuli (39).

Under the inflammatory conditions associated with the pathophysiology of head pain (including temporomandibular disorder, facial pain and migraine), the tissue damage that leads to release of inflammatory mediators such as extracellular proton (H^+), bradykinin (BK), nitric oxide (NO), prostaglandins (PGE_2), nerve growth factor (NGF), and adenosine triphosphate (ATP) that activate nociceptors (2, 16, 41-44). Similarly, cortical spreading depression (CSD), a depolarizing wave that occurs during migraine attack also leads to release of inflammatory mediators including H^+ , arachidonic acid (AA), NO, and potassium (K^+) from cerebral cortex to the extracellular fluid. CSD increases matrix metalloproteinases 9 (MMP-9) level to interrupt blood- brain barrier (BBB), and then activates the nociceptive afferent at pial and dural vessels (45, 46). These mediator stimuli are transduced by a transducer protein or various transducer proteins. For example, the extracellular H^+ activates acid sensing ion channels (ASICs) and/or transient receptor potential vanilloid 1 (TRPV1) that transduce signal to electrochemical impulses (47). The impulse is transmitted along the nociceptive axon and synapses on the neurons in the superficial layer (laminae I and II) that terminated by C-fiber, and the deeper layer (laminae III and IV) that are terminated by A-delta fiber, of the trigeminal nucleus caudalis (TNC) and C1-C3 spinal dorsal horn (48, 49). Moreover, the TNC and C1-C3 cervical cords are grouped and referred to the trigeminocervical complex (TCC) (50). The neurons in the TCC are classified into wide dynamic range (WDR) which respond to innocuous stimuli at deep layer, and nociceptive specific (NS) which respond to noxious stimulus, neurons that mainly locate at superficial layers (51, 52). The impulses from these neurons in the TCC give ascending fibers that decussate and convey information to the third-order neurons in the ventromedial thalamic nucleus (VPM) of thalamus and medial nucleus of the posterior group intralaminar complex via trigeminothalamic tract (or known as quintothalamic tract). The third-order neurons project thalamocortical axon to the facial region in the primary

somatosensory cortex that translate impulses into the perception of pain or headache (53).

In addition to CNS transmission, meanwhile, the nociceptors synthesize vasoactive neuropeptides such as CGRP and substance P (SP) in the cell body and transport them to peripheral terminal. These neuropeptides cause the neurogenic inflammation and sensitization in head pain (54).

Neurogenic inflammation

Neurogenic inflammation is mediated by CGRP and SP. CGRP is proposed to play a role in the initiation of this inflammation (55, 56). In the peripheral afferent within high density of blood vessels, SP produces plasma protein extravasation, while CGRP produces vasodilation and mast cell degranulation (57-59). Moreover, CGRP also activates the satellite glia cells, which locate around trigeminal ganglion neurons (60). Both the mast cell degranulation and SGC activation lead the release of pro-inflammatory mediators and cytokines that contribute to the nociceptor sensitization (61). The mast cells locate near meningeal nociceptors and blood vessels, temporomandibular joint, buccal mucosa, tongue, palate, as well as cutaneous tissues (62, 63). The activation of the mast cells by neuropeptides, especially CGRP, causes its degranulation that leads to release of histamine, bradykinin, nerve growth factor (NGF), serotonin, as well as the cytokines including, interleukin-1 (IL-1), IL-6, and tumor necrosis factor-alpha (TNF-alpha) resulting in nociceptors activation and enhancement of neuronal excitability (61-64). Moreover, the mast cell degranulation can produce a prolonged excitation in the nociceptors, especially C-fiber, that is long-lasting at least 4 hour and causes *c-fos* expression in TNC nociceptive neurons (65). In addition to the mast cells, SGC is another one in response to CGRP and causes neurogenic inflammation (23). SGC activation leads to release of TNF-alpha, IL-1beta, and prostaglandin E₂ (PGE₂), that activate the nociceptors and enhance neuronal excitability (24, 66). In summary, mast cells degranulation is an important process in the peripheral nociception, and SGCs activation is also an important

process in cell bodies sensitization that are involved in the development of peripheral sensitization (61).

Calcitonin gene-related peptide (CGRP) and its receptor

CGRP, a 37 amino acid vasodilatory neuropeptide, is a member of the calcitonin family, had been identified by Rosenfield in 1983. CGRP is classified into alpha-CGRP, which expresses in the nervous system (peripheral and central nervous system: PNS and CNS, respectively), and beta-CGRP, which expresses in the enteric nervous system (ENS) and pituitary gland. Alpha-CGRP and beta-CGRP isoforms are not difference in their biological activities, however, they differ in the sequence of amino acids (67). CGRP affects CGRP receptor that consists of calcitonin-like receptor (CLR), a seven-transmembrane G-protein-coupled receptor, interacting with receptor activity-modifying proteins 1 (RAMP1), a small single-transmembrane protein, and receptor component protein (RCP), an accessory protein (67). CLR require both RAMP1 and RCP to form a functional unit that RAMP1 transports CLR to plasma membrane as a mature glycoprotein and facilitates CGRP binding, while RCP directly binds to CLR, and facilitates the coupling of CGRP receptor to the intracellular signaling pathways (68, 69).

Distribution of CGRP and its receptor

CGRP and its receptor express in the nervous, cardiovascular, respiratory, and gastrointestinal systems (70, 71). In the peripheral nervous system (PNS), CGRP and its receptor are distributed in distinctive location. CGRP expresses on unmyelinated nerve fibers (defined as C-fibers) which are small-to-medium- sized neurons projecting to the spinal trigeminal region and superficial laminae (I and II) of the spinal trigeminal nucleus and C-1 of spinal cord level. In the other way, CGRP receptor (CLR+RAMP1) expresses on myelinated nerve fibers (defined as A-delta fibers) which are large-sized neurons, also projecting to the spinal trigeminal tract region and laminae I and II of the spinal trigeminal nucleus and C-1 of spinal cord

level. In addition to neurons, CGRP receptor, but not CGRP expresses on medial vascular smooth muscle layer, mast cells, and SGCs (72-74). Moreover, CGRP is co-expressed with synaptosomal-associated protein of 25 kDa (SNAP-25) in all regions of C-fiber neurons that SNAP-25 facilitates CGRP vesicle trafficking and CGRP secretion resulting in a paracrine signaling manner to activate blood vessels, mast cells, SGCs, and A-delta fibers (25, 75). Generally, CGRP and its receptor are not co-localized in the same neurons, however there is rare case that they are co-localized as auto-receptor (interaction with CGRP and its receptor in the same neurons) (25, 76). Thus, CGRP acts as a mediator in the intraganglionic communication between neurons and non-neuronal cells for neurogenic inflammation and peripheral sensitization as well as for relaying nociceptive information to higher-order neurons in brain (22, 77).

CGRP receptor-mediated signal transduction and peripheral sensitization

In the trigeminal nociception, the activation of CGRP receptor is induced by CGRP that couples to the intracellular signaling cascade and phosphorylates ion channels via protein kinase A (PKA), PKC, Ca^{2+} / calmodulin-dependent kinases II (CaMKII) and mitogen-activated protein kinase (MAPK) pathways.

In the PKA pathway, the CGRP receptor activation couples to the signal transduction via $G_{\alpha_{\text{pha-s}}}$ protein that is commonly affected in neural function. The activated $G_{\alpha_{\text{pha-s}}}$ protein stimulates adenylyl cyclase (AC) that produces cyclic adenosine monophosphate (cAMP) resulting in PKA activation (69). The targets of PKA activation are ion channels and cAMP response element binding protein (CREB) that involves in physiological and neuronal effects. The vasodilation occurs under the activation of CGRP receptor on vascular smooth muscle cells via cAMP and PKA stimulation (78). Moreover, PKA is the important signal in the regulation of auto-activated receptor that it enhances CGRP promoter activity and then results in transcribing CGRP mRNA. This causes CGRP self-regulated sensitization and auto-regulation is upon on the expression of RAMP1 (79). The effect of CGRP on an ion channels has been studied in $P2X_3$ receptor. CGRP activated $P2X_3$ receptor trafficking via PKA. $P2X_3$ receptor is phosphorylated and translocated from the intracellular

stores to the surface of neuronal membrane (19). Moreover, PKA phosphorylates CREB, a gene regulatory protein that results in increase of P2X₃ mRNA expression (80). Thus, CGRP sensitizes the trigeminal ganglion neurons via PKA pathways.

In the PKC and CaMKII pathways, the signal transduction is mediated by G_αq/11 protein which activates the phospholipase C-beta (PLC-beta) to hydrolyze phosphatidylinositol 4,5-bisphosphate (PIP₂) into inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ bind to IP₃-gated Ca²⁺-release channel (IP₃ receptor) on endoplasmic reticulum (ER) which releases Ca²⁺ into the cytoplasm, whereas DAG modulate intracellular Ca²⁺ which activates the PKC, and PKC further phosphorylates ion channels (81, 82). PKC also phosphorylates and inserts P2X₃ receptor from the cytoplasm to the membrane surface (19). Moreover, intracellular Ca²⁺ binds to calmodulin, and activates Ca²⁺ / calmodulin-dependent kinases II (CaMKII), and then CaMKII phosphorylates CREB and increase P2X₃ mRNA (80). These suggest that CGRP increases the intracellular Ca²⁺ via G_αq/11 protein and sensitize P2X₃ receptor via PKC and CaMKII.

MAPK cascades including ERK, JNK, and p38 expression, are up-regulated by CGRP that activates CGRP receptor on SGCs (83, 84). SGCs release cytokines that activate TG neurons causing the peripheral sensitization (23). However, the mechanism whether CGRP receptor couples MAPK signaling is still unclear. It may be depended on whether G_αq/11 or other mechanisms (82).

In summary, the activation of CGRP receptor produces strong and prolonged pain that causes peripheral sensitization via the phosphorylation of ion channels and target proteins by PKA, PKC, CaMKII and MAPK (44, 83). Thus, CGRP sensitizes receptor or ion channel via the intracellular signaling pathway that leads to prolonged headache. However, the relationship between CGRP and ASICs are still unexplored.

Acid-sensing ion channels (ASICs)

The inflammatory events associated with the pathophysiology of head pain and lead to a local tissue acidosis. The high concentrations of proton (H⁺) can reduce

pH value from physiological pH (pH 7.4) to pH 5.4 (3). Pain is evoked by extracellular H^+ that opens cation channel in nociceptors (1, 4). The receptors of extracellular H^+ are acid-sensing ion channels (ASICs) and transient receptor potential vanilloid type 1 (TRPV1), and they have different sensitivity to pH values (34). In the aspect of sensitivity to pH change, ASICs are more sensitive than TRPV1. ASICs require pH change only from pH 7.4 to pH 7.0 for its activation, while TRPV1 requires pH change from pH 7.4 to pH 6.0 (5, 6). Thus, ASICs are main sensor to detect acidic noxious in the tissue acidosis.

ASICs, which had been cloned by the Waldmann and colleague, are trimeric voltage-independent ligand-gated cation channels and mainly permeable to sodium ions (Na^+) (7, 85). The structure of one subunit (monomeric) of ASICs consists of two hydrophobic transmembrane domains, intracellular N- and C-termini, and large extracellular loop with the conservative of cysteine-rich (86). There are six ASICs that consist of ASIC1 which is spliced into ASIC1a (85, 87) and 1b (9, 88), ASIC2 which is also spliced into ASIC2a (89, 90) and 2b (91), ASIC3 (dorsal root ASIC or DRASIC) (92), and ASIC4 (spinal cord ASIC or SPASIC) (93). However, ASIC4 is excluded, because it cannot function as H^+ -gated cation channels (93).

The distribution of ASICs in nervous system

ASICs widely express on neurons in both central and peripheral nervous system (CNS and PNS). In the CNS, ASIC1a, 2a and 2b express in whole brain including the cerebral cortex, cerebellum, hippocampal formation, amygdaloid nuclei, hypothalamus, and basal ganglia, whereas, in the PNS, ASIC1a, 1b, 2b, and 3 are expressed on sensory neurons (9, 85, 89-92, 94). In TG, there are the expression of both ASIC1a and 3 which are specific on individual size of neurons. ASIC1a and 3 express on small-to-medium-sized neurons, and respond to noxious stimuli, while ASIC3 is also expressed on large-sized neurons, and have mechanoreceptor and proprioceptor properties (9-11, 16).

Biophysical properties of ASICs

The distinct properties of ASICs are dependent on assembly of 3 subunit compositions that forms homomultimeric or heteromultimeric channels. ASICs have permeability to $\text{Na}^+ > \text{Ca}^{2+} > \text{K}^+$, however, the selective permeability is various depending on types of ASICs. For example, ASIC1a has permeability to Na^+ and Ca^{2+} , while ASIC1b has not any permeability to Ca^{2+} (88, 95).

The pH sensitivity of ASICs is obtained from the values of the half-maximal activation ($\text{pH}_{0.5}$), is 5.8-6.8, 6.1-6.2, 4.5-4.9, and 6.4-6.6 for ASIC1a, 1b, 2a, and 3 homomultimeric channels, respectively (96, 97). However, ASIC2b cannot form homomultimeric channel function by itself. In acid-evoked current, ASICs generate transient inward current, which followed by rapidly desensitization that is sustained current in which occurring after the desensitization is almost completed. The order of time constant for desensitization is $\text{ASIC2a} > \text{ASIC1b} > \text{ASIC1a} > \text{ASIC3}$, while the order of percentage from sustained current to peak current is $\text{ASIC3} \gg \text{ASIC2a} > \text{ASIC1b} > \text{ASIC1a}$ (97). These correlate to the shape of ASICs current. Moreover, ASIC3 is the important channel for displaying a sustained pain. ASIC3 responds the slightly continuous drop pH to pH 4.0 that generates only sustained current and produces the long-lasting sensation of pain (1, 92). ASICs transduce the chemical signal to electrical signal for transmission that associates with action potentials (APs). APs which elicited by pH change, are induced during transient inward current. This suggests that Na^+ influx through ASICs play the major role in producing APs (14).

Neuropeptides modulate ASICs

The neuropeptides which modulate ASIC1 and 3 in dorsal root ganglion (DRG) neurons are Phe-Met-Arg-Phe (FMRF)amide, neuropeptide SF (Ser-Leu-Ala-Ala-Pro-Gln-Arg-Phe-amide, NPSF), and neuropeptide FF (Phe-Leu-Phe-Gln-Pro-Gln-Arg-Phe-amide, NPFF) (98). These neuropeptides directly activate ASIC1 and 3 that ASIC3 is a major response resulting in an increase of peak amplitude of transient inward current, an increase of time constant of desensitization, and an induction of sustained current (99-102). Moreover, these neuropeptides also modulate ASIC1 and ASIC3 that

increase the neuronal excitability under the acidosis of inflammation (101). Thus, FMRFamide, NPSF, and NPF modulate ASICs to produce the excitability of nociceptors under the inflammatory events. However, the other neuropeptides including SP and CGRP do not effect on ASICs mRNAs level (103). Moreover, the effect of SP and CGRP on ASICs properties is unclear and should be clarified in the future.

The relationship of ASICs and CGRP

The implication between ASICs and CGRP has been studied by the aspects of localization and modulation. In the study of localization, it has been revealed that ASICs and CGRP are co-expressed on small-to-medium-sized neurons in DRG and TG (10, 11). When the extracellular H^+ activates ASICs on TG neurons, Na^+ will fluxes into neurons that increase the levels of intracellular Na^+ . The elevation of intracellular Na^+ promotes the release of CGRP (21). However, the co-expression of CGRP receptor and ASICs are unknown. Indeed, CGRP receptor expresses on large-sized TG neurons that is similar to ASIC3 (10, 25). Because of the difference in pattern expression, the effect of CGRP on ASICs in TG neurons may differ depending on cell phenotype.

CHAPTER III

MATERIALS AND METHODS

MATERIALS

1. Chemicals

Adenosine 5 ¹ -triphosphate magnesium salt (Mg-ATP)	Sigma-Aldrich, MO, USA
Calcium chloride (CaCl ₂)	Merck, Germany
Ethylenglycol-bis- (2-aminoethylethyl)- tetraacetic acid (EGTA)	Sigma-Aldrich, MO, USA
Glucose	Sigma-Aldrich, MO, USA
Guanosine 5 ¹ -triphosphate sodium salt hydrate (Na-GTP)	Sigma-Aldrich, MO, USA
HEPES free acid	Sigma-Aldrich, MO, USA
Laminin	Sigma-Aldrich, MO, USA
Magnesium chloride (MgCl ₂)	Sigma-Aldrich, MO, USA
Poly-d-lysine (PDL) hydrobromide	Sigma-Aldrich, MO, USA
Potassium chloride (KCl)	Sigma-Aldrich, MO, USA
Potassium gluconate (K-gluconate)	Sigma-Aldrich, MO, USA
Potassium hydroxide (KOH)	Merck, Germany

Sodium chloride (NaCl) Sigma-Aldrich, MO, USA

Sodium hydroxide (NaOH) Merck, Germany

2. Drugs

Alpha-calcitonin gene-related

peptide (alpha-CGRP) Sigma-Aldrich, MO, USA

Sodium pentobarbital Ceva Sante Animale, Libourne, France

3. Media

Collagenase type IV Invitrogen, Carlsbad, CA, USA

Dispase II Invitrogen, Carlsbad, CA, USA

Fetal bovine serum (FBS) Gibco, Grand Island, NY, USA

Glutamax Gibco, Grand Island, NY, USA

Ham's F-12 Gibco, Grand Island, NY, USA

Hank's balanced salt solution

(HBSS) Gibco, Grand Island, NY, USA

Leibovitz's L-15 medium (L-15) Gibco, Grand Island, NY, USA

Papain Sigma-Aldrich, MO, USA

Penicillin (10000 U/ml)/

Streptomycin (10000 µg/ml) Gibco, Grand Island, NY, USA

4. Materials

Borosilicate glass pipettes	
(1.5 mm OD × 0.86 mm ID)	Sutter Instruments, Navato, CA, USA
Calibrate graticule	Pyser, Kent, UK
Glass pasteur pipette	BRAND, Wertheim, Germany
35 mm × 10 mm dish	Corning, NY, USA

5. Instrumental devices

Bravia LCD TV BX300	Sony Thai Co., Ltd, Thailand
BX51WI fixed-stage upright	
microscope	Olympus Corporation, Japan
CelCulture CO ₂ incubator	Esco Global, Singapore
Class II biological safety cabinet	
model AC2	Esco Global, Singapore
Digitdata 1440 series interface	Axon Instruments, Foster City, CA, USA
Flaming/Brown micropipette	
puller (P-97)	Sutter Instruments, Navato, CA, USA
Fiske® 210 Micro-osmometer	Advanced Instruments, Inc., MA, USA
High output vacuum/pressure	
pump	EMD Millipore Corporation, MA, USA
MP-385-2 Micromanipulator	Sutter Instruments, Navato, CA, USA
Narishige MF-830 microforge	Narishige, Japan

Patch clamp amplifier:

Axopatch 200B Axon Instruments, Foster City, CA, USA

Peristaltic pump: Minipuls 3 Gilson, S.A.S., Villiers le Bel, France

Rotina 420 R Hettich Instruments, Bäch, Switzerland

Software for data acquisition:

Clampex 10.2 Axon Instruments, Foster City, CA, USA

Software for data analysis:

pClampfit 10.2 Axon Instruments, Foster City, CA, USA

Super HAD CCD II camera Sony Corporation, Japan

Vibration isolation platform Newport Corporation, CA, USA

EXPERIMENTAL DESIGN

The aim of this study is to determine the effect of pH 7.0 on ASICs in small-to-medium-sized and large-sized neurons. Moreover, we aim to investigate the modulation of CGRP on ASICs activity in small-to-medium-sized neurons and large-sized neurons. Thus, the experiments were separated into 2 major parts as described below.

1. Experiment I

The effect of pH 7.0 on phenotypes of trigeminal ganglion neurons was studied by using whole-cell patch-clamp configuration. The experiment was *in vitro* study. TG neurons were divided into 2 groups; small-to-medium-sized (n = 19) and large-sized neurons (n = 6). Both groups of neurons were superfused by the 2 types of extracellular solution that were physiological pH (pH 7.4) and low pH (pH 7.0). The extracellular solution was changed from pH 7.4 to pH 7.0 within 10 minutes. After lowering pH, the variables of the neuronal properties and AP shapes were measured and compared within their groups.

Figure 3.1 Diagram of experimental design of the experiment I.

2. Experiment II

The effect of CGRP on ASICs on phenotypes of trigeminal ganglion neurons was studied by using whole-cell patch-clamp configuration. The experiment was *in vitro* study. The experiment was *in vitro* study. TG neurons were divided into 2 groups; small-to-medium-sized (n = 9) and large-sized neurons (n = 6). Before recording, both groups of neurons were incubated with 1 μ M CGRP in pH 7.4 for 1 hour at the room temperature. Next, the extracellular solution was changed to pH 7.0 with 1 μ M CGRP that incubated for 10 minutes at the room temperature. The variables of the neuronal properties and AP shapes were measured and compared within in their groups.

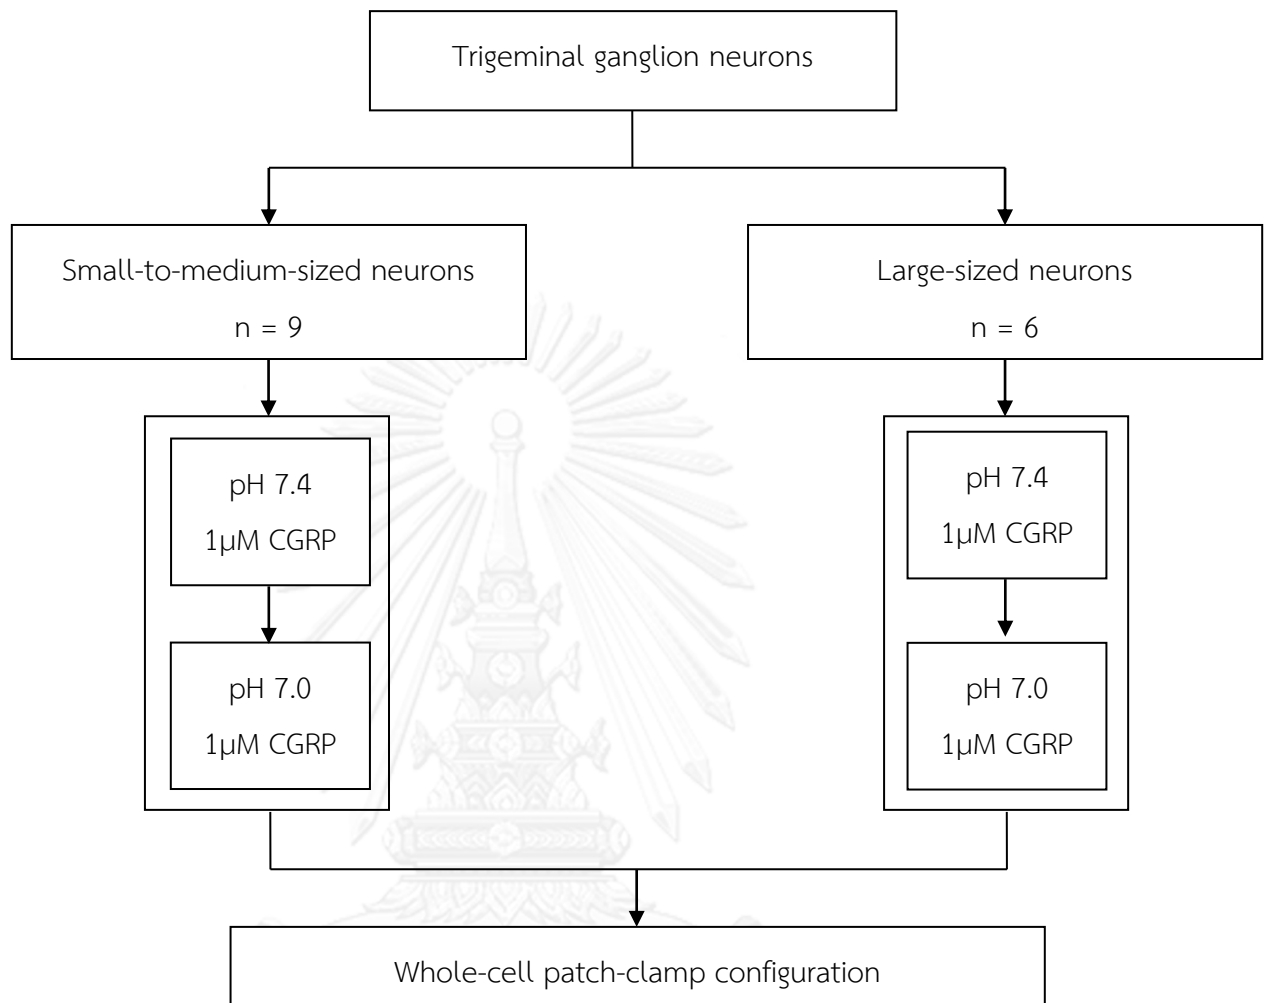

Figure 3.2 Diagram of the experimental design of the experiment II.

METHODS

1. Animals

Adult male Wistar rats were purchased from the National Laboratory Animal Center (Mahidol University, Salaya, Nakhonpathom, Thailand). Rats were maintained in a ventilated room on a 12 h dark/light cycle with free access to food and water in accordance with procedures approved by the Animal Care and Use Committee (Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand).

2. Primary Culture

Trigeminal ganglion (TG) neurons were obtained from 4- to 8-week-old rats using a previously described dissociation protocol (104) with minor modifications as follows. Rats were euthanized by intraperitoneal injection of an overdose of sodium pentobarbital (Ceva Sante Animale, Libourne, France) and decapitated. Trigeminal ganglia were excised and transferred to a Petri dish containing ice-cold Hank's balanced salt solution without $\text{Ca}^{2+}/\text{Mg}^{2+}$ (HBSS, Gibco, Grand Island, NY) and chopped into small pieces. After digestion in HBSS containing 10 mg ml^{-1} collagenase type IV (Invitrogen, Carlsbad, CA) and 18.2 U ml^{-1} dispase type II (Invitrogen) for 20 minutes at 37°C followed by HBSS containing 1.5 mg papain (Sigma, St. Louis, MO) for 20 minutes at 37°C , pieces of ganglia were triturated by passing them through sterilized fire-polished Pasteur pipette in L-15 medium (Gibco) containing 4.8% fetal bovine serum (FBS, Gibco), $10,000 \text{ units ml}^{-1}$ of penicillin and $10,000 \mu\text{g ml}^{-1}$ of streptomycin (Gibco) and 1 M HEPES (Sigma). Dissociated neurons were spun at 1000 rpm to sediment the neurons. The neuronal cell pellet was resuspended in Ham's F-12 (Invitrogen) containing 10% FBS, $10,000 \text{ units ml}^{-1}$ of penicillin and $10,000 \mu\text{g ml}^{-1}$ of streptomycin, and Glutamax (Gibco), and then plated onto 35 mm Petri dishes precoated with poly-d-lysine (PDL, Sigma) and laminin (Sigma). Neurons were maintained in an incubator at 37°C under an atmosphere of 5% CO_2 and used within 24–48 h after plating.

Soma diameters, were classified into small (<30 μm), medium (30–40 μm), and large (>40 μm) diameter neurons shown in **Figure 3.3**, as measured using a calibrated graticule (Pyser, Kent, UK) before whole-cell patch-clamp recordings.

Figure 3.3 Representative neurons, small-sized (23.40 μm , **A**), medium-sized (35.25 μm , **B**) and large-sized neurons (41 μm , **C**). These neurons were measured using a 40 \times objective lens. Scale bars all 10 μm .

3. Electrophysiological recording

Neurons were superfused at flow rate 2 ml min⁻¹ with an extracellular solution containing 145 mM NaCl, 5 mM KCl, 2 mM CaCl₂, 1 mM MgCl₂, 10 mM d-Glucose, and 10 mM HEPES, pH 7.4 (adjusted with NaOH) and whole-cell patch-clamp recording was performed using an Axopatch 200B amplifier (Axon instruments, Foster City, CA) and pClamp 10 acquisition software (Axon instrument, City, ST). Borosilicate glass pipettes (1.5 mm OD \times 0.86 mm ID, Sutter Instruments, Navato, CA) were pulled by using a Flaming–Brown micropipette puller (P-97, Sutter Instruments) and had resistance of 2–5 M Ω when polished with microforge (MF-830, Narishige, Japan) and filled with an internal solution containing 140 mM K-gluconate, 1 mM CaCl₂, 2 mM MgCl₂, 10 mM EGTA, 10 mM HEPES, 0.3 mM Na-GTP, and 10 mM Mg-ATP, pH 7.3 (adjusted with KOH). Neurons were voltage clamped at -60 mV and current was filtered at 5 kHz (using a low-pass filter) and sampled 25 kHz by using a Digidata 1440 series interface (Axon instruments). After whole-cell voltage clamp was established, the clamp switched to current clamp mode, which measured the resting membrane potential (RMP) with no applied current. Following and adapting a protocol described previously (105), applying short (1 ms) and long (500 ms)

depolarizing current pulses with -65 mV of holding potential (HP), to assess the action potential shape and the excitability of neurons, respectively. After recording in the extracellular solution at physiological pH (pH 7.4), to evaluate the effect of low pH, the extracellular solution was changed to pH 7.0. The time to change the solution was approximately 10 minutes.

The effect of CGRP on ASICs was evaluated, we dissolved alpha-CGRP (Sigma) in double-distilled water (ddH₂O) and added the alpha-CGRP solution to the extracellular solution at both pH 7.4 and 7.0 such that the final concentration of CGRP in each solution was 1 μ M, as described in the previous study (19).

4. Action potential parameter assessments

When applying the 500 ms of current to define the excitability of neuron, threshold and rheobase were measured. Threshold was considered as the depolarizing potential that triggered the first AP (black dot, **Figure 3.4**) while the rheobase was the lowest injecting current that produced an AP (arrow, **Figure 3.4**). Total spikes was the number of spikes that triggered by depolarizing step currents from the 5th to 21st steps with increasing 5 pA per step.

A brief (1 ms) current was injected to assess the AP shape (**Figure 3.5**). AP height (AP_{height}) was measured from the membrane potential (E_m) to the peak of the AP, while AP overshoot (AP_{overshoot}) was measured at 0 mV to the peak of the AP. AP rising time (AP_{RT}) was measured from the threshold to the peak of the AP and the AP falling time (AP_{FT}) was measured from the peak to the E_m , whereas AP duration (AP_{duration}) was the sum of the rising and falling times (**Figure 3.5**). The depth of after-hyperpolarization (AHP_{depth}) was determined from the E_m to the peak of the AHP, while the duration of the AHP was measured from the peak of the AHP to 50% of recovery to the baseline (AHP₅₀) (**Figure 3.6**).

Figure 3.4 Measurement of threshold and rheobase. Upper: Threshold was measured at black dot with value as -21.63 mV, while rheobase was measured at first spike with value of 35 pA. Lower: The depolarizing current steps were injected to evoke the action potential, which first spike was evoked by the 11^{th} step with value of 35 pA (arrow).

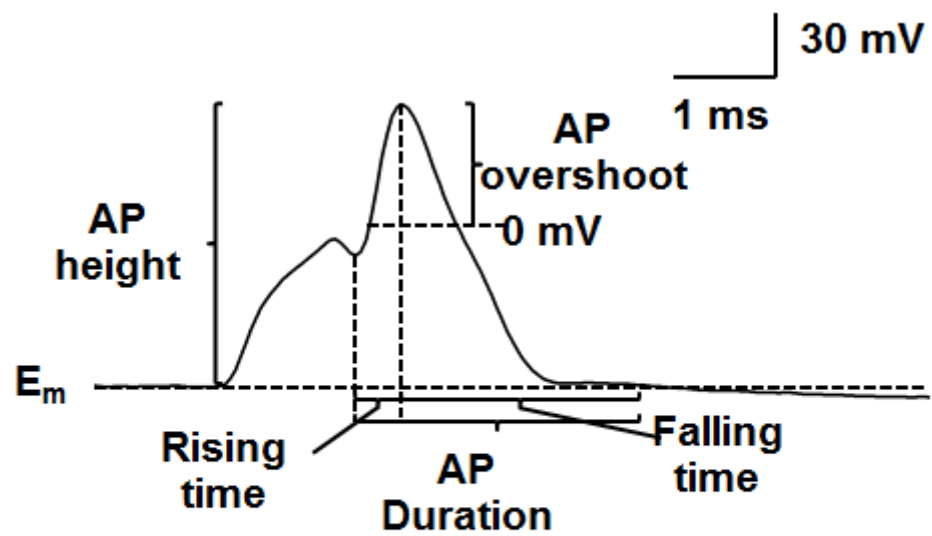

Figure 3.5 The illustration shows that the action potential (AP) parameters were assessed by injected 1ms current. The AP parameters; height, overshoot, rising time, falling time, and duration were recorded. E_m was membrane potential.

Figure 3.6 The illustration shows that the after-hyperpolarization (AHP) parameters were assessed with depth of AHP and duration at half of recovery to baseline of AHP (AHP_{50}). E_m was membrane potential.

5. Data analysis

All data are presented as mean \pm standard errors of means (SEM). Statistical analysis was performed using Student's *t* test (Sigma Plot version 10.0, City, State, USA). $P < 0.05$ was accepted as statistically significant.

CHAPTER IV

RESULTS

Effect of pH 7.0 on the small-to-medium-sized TG neurons

Depolarizing current pulses with 500 ms were applied to small-to-medium-sized neurons (<40 μm ; $n = 19$) before and after decreasing the pH from physiological (pH 7.4) to pH 7.0 as shown in representative trace (**Figure 4.1**). The RMP was significantly depolarized at pH 7.0 (**Figure 4.2** and **Table 4.1**). Small-to-medium-sized neurons tended to produce more spikes, but this change was not significant compared to control (**Figure 4.3**). Totally, small-to-medium-sized neurons were excited in response to low pH (**Table 4.1**). Their threshold was significantly shifted to more negative at pH 7.0 (**Figure 4.4**) and rheobase was significantly decreased (**Figure 4.5**).

Action potential (AP) shapes and variables were measured by applying a 1 ms depolarizing current pulse (**Table 4.1**). The AP_{height} at physiological pH was significantly smaller than control at pH 7.0 (**Figure 4.6**), and the $AP_{\text{overshoot}}$ was also significantly smaller than control (**Figure 4.7**). The magnitude of the AHP_{depth} of the neurons was significantly decreased at pH 7.0 (**Figure 4.8**), while the AHP_{50} was significantly longer than control at pH 7.0 (**Figure 4.9**). However, there were no changes in the AP_{duration} (**Figure 4.10**), AP_{RT} (**Figure 4.11**), or AP_{FT} (**Figure 4.12**) in response in physiological pH and low pH.

Effect of pH 7.0 on the large-sized TG neurons

Depolarizing current pulses with 500 ms were applied to the large-sized neurons ($>40 \mu\text{m}$, $n = 6$) before and after decreasing the pH from physiological (pH 7.4) to low pH (pH 7.0) as shown in representative traces (**Figure 4.13**). The RMP was not significantly different between physiological pH and pH 7.0 (**Figure 4.14** and **Table 4.2**). Responding neurons were not significantly excitable at pH 7.0 (**Table 4.2**). There was no significant difference between the numbers of spikes during pH change (**Figure 4.15**). Moreover, the threshold was not changed at pH 7.0 (**Figure 4.16**), and the rheobase was also unchanged at pH 7.0 (**Figure 4.17**).

There were no significant differences in the variables of AP shape (**Table 4.2**). The AP_{height} was not changed at pH 7.0 (**Figure 4.18**) and the $AP_{\text{overshoot}}$ was also not changed at pH 7.0 (**Figure 4.19**). Similarly, the AHP_{depth} was not changed at pH 7.0 (**Figure 4.20**) and the AHP_{50} was also not changed at pH 7.0 (**Figure 4.21**). Moreover, the AP_{duration} (**Figure 4.22**), AP_{RT} (**Figure 4.23**), and AP_{FT} (**Figure 4.24**) were not significantly changed in response to pH.

Effect of CGRP in modulating pH 7.0 on the small-to-medium-sized neurons

Depolarizing current pulses with 500 ms were applied to the small-to-medium-sized neurons ($<40 \mu\text{m}$, $n = 9$) treated with CGRP before and after decreasing the pH from physiological (pH 7.4) to pH 7.0 as shown in representative trace (Figure 4.25). The RMP was significantly shifted to more negative when pH was decreased from physiological pH to pH 7.0 (Figure 4.26 and Table 4.3). There was no significant difference between the numbers of spikes before and after decreasing the pH (Figure 4.27). The threshold at physiological pH was shifted to less negative at pH 7.0 (Figure 4.28), while the rheobase of current at physiological pH was decreased at pH 7.0 (Figure 4.29), but this was not significantly different (Table 4.3).

The AP_{height} at physiological pH was significantly reduced when pH was change to pH 7.0 (Figure 4.30) and the $AP_{\text{overshoot}}$ was significantly reduced (Figure 4.31). The AHP_{depth} was significantly increased (Figure 4.32), while the AHP_{50} showed no difference between physiological pH and pH 7.0 (Figure 4.33). There were no significant difference in the AP_{duration} (Figure 4.34) and AP_{FT} (Figure 4.35). By contrast, the AP_{RT} at physiological pH was significantly longer at pH7.0 ((Figure 4.36 and Table 4.3).

Effect of CGRP in modulating pH 7.0 on the large-sized neurons

Depolarizing current pulses with 500 ms were applied to the large-sized neurons ($>40 \mu\text{m}$, $n = 6$) that were applied with CGRP in physiological pH (pH 7.4) compared to low pH (pH 7.0) (Figure 4.37). The RMP was not changed at pH 7.0 (Figure 4.38 and Table 4.4). Large-sized neurons in pH 7.4 showed significantly less spikes at than at pH 7.0 (Figure 4.39). The threshold was not significantly changed (Figure 4.40), but the rheobase of current at pH 7.4 was significantly decreased comparing with at pH 7.0 (Figure 4.41 and Table 4.4).

The AP_{height} at physiological pH was not significantly changed at pH 7.0 (Figure 4.42) and the $AP_{\text{overshoot}}$ was also not significantly changed at pH 7.0 (Figure 4.43). The AHP_{depth} was not significantly changed at pH 7.0 (Figure 4.44) and the AHP_{50} was also not changed at pH 7.0 (Figure 4.45). Moreover, the AP_{duration} (Figure 4.46), AP_{RT} (Figure 4.47), and AP_{FT} (Figure 4.48) were not significantly changed in response to pH 7.0 (Table 4.4).

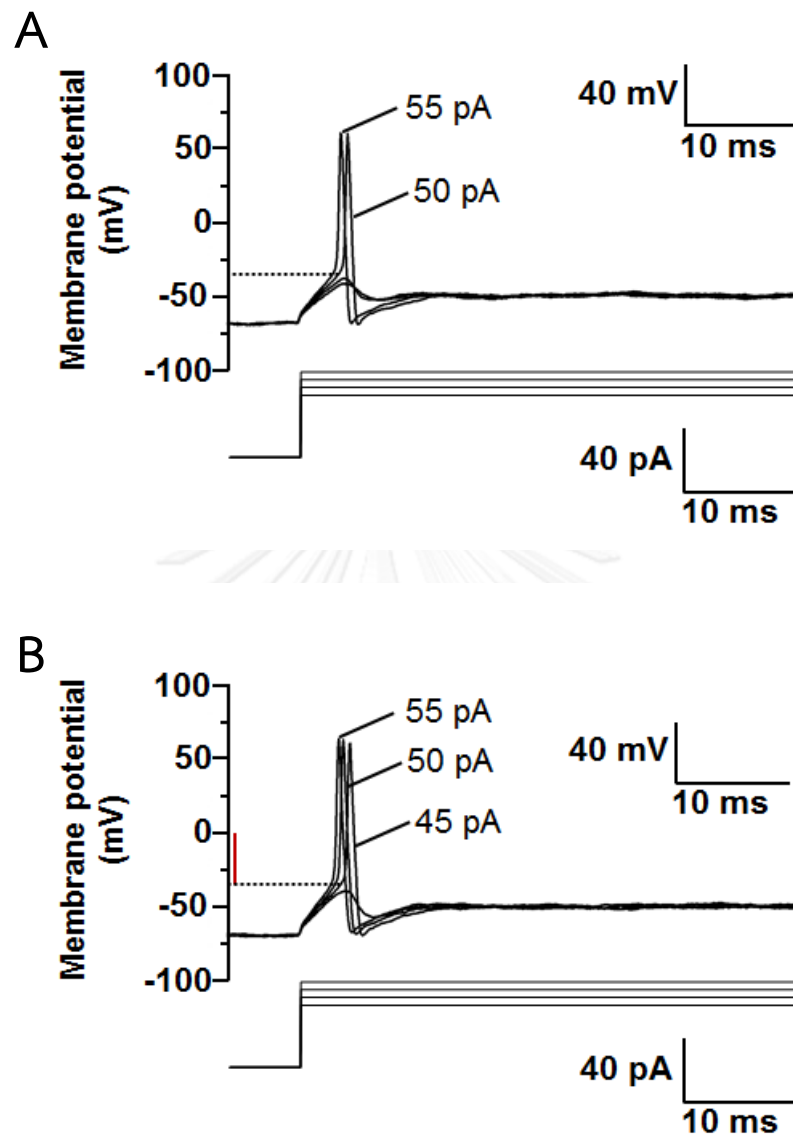

Figure 4.37 Representative traces show the neuronal excitability of large-sized neurons that responded to physiological pH (7.4) and low pH (pH 7.0) with CGRP application. **A.** Response of a large-sized neuron to pH 7.4 showing a threshold of -34.74 mV and a rheobase of 50 pA. **B.** Response of a large-sized neuron to pH 7.0 showing a threshold of -34.43 mV and a rheobase of 45 pA.

CHAPTER V

DISCUSSIONS

The present study had purposed to demonstrate the effect of CGRP on ASICs in trigeminal ganglion neurons.

Effect of pH 7.0 on the small-to-medium-sized TG neurons

Extracellular proton (pH 7.0) alters an excitability of small-to-medium-sized neurons by depolarizing RMP, reducing threshold and rheobase. Moreover, extracellular proton also changes AP shapes by decreasing height and overshoot, as well as reducing the depth of AHP and lengthening the duration of AHP₅₀.

RMP is generally stabilized by two-pore potassium channel (K2P) or called 'leak-channel', voltage-gated sodium channels 1.9 (Na_v1.9), and voltage-gated potassium channels 7.2-7.3 (K_v7.2-7.3). These channels are activated at membrane potential near RMP or below, especially K2P that is activated at more negative membrane potential than the others (106-108). Our results showed that RMP was depolarized by pH 7.0. This indicated that the effect of extracellular proton inhibits subtypes of K2P, which were TWIK (two pore domain potassium channel)-related acid sensitive K⁺ channel 3 (TASK-3) and TWIK-related spinal cord K⁺ channel (TRESK), and then potassium (K⁺) ions cannot efflux or leak out through these channels resulting in accommodation of intracellular K⁺ ion (109-111). Meanwhile, extracellular proton activates ASICs resulting in the Na⁺ passing into neurons (21, 85). The accommodation of intracellular Na⁺ and K⁺ shifts RMP value to more positive, therefore neuronal excitability is increased.

Threshold is the critical level that the inward Na⁺ ion exceeds the outward K⁺ and Cl⁻ ions. This depolarization causes the activation of voltage-gated sodium channels (Na_v) and AP induction. Incidentally, rheobase (threshold current) is the value of injected current that shift membrane potential to threshold. The subtypes of Na_v channels which regulated depolarization toward threshold are Na_v1.7 and 1.9 channels (112, 113). These channels are activated under the threshold (or called

‘subthreshold’), and they shift membrane potential closing to threshold for opening $\text{Na}_v1.8$ that produces upstroke of AP (112). Our results showed that threshold was decreased to more negative and rheobase was reduced in the condition of pH 7.0. These may cause from an up-regulation of $\text{Na}_v1.9$, which may be regulated via ASICs signaling pathway. This indication is similarly to effect of PGE_2 that up-regulated $\text{Na}_v1.9$ via G-proteins signaling (114, 115). Moreover, threshold decreasing and rheobase reduction may be the result of an internal dialysis of GTP that modulates and up-regulates $\text{Na}_v1.9$ (116). Interestingly, we used GTP in an intracellular solution (see the methods) and shifted the pH from 7.4 to 7.0 approximately 10 minutes that GTP would be internally dialyzed. Indeed, the effect the internal dialysis of GTP on threshold and rheobase has been investigating (117). In addition to $\text{Na}_v1.9$, the up-regulation of $\text{Na}_v1.7$ under inflammatory condition can reduce rheobase and amplifying sub-threshold depolarization to reach the threshold of $\text{Na}_v1.8$ for producing AP (112). Thus, under the condition of pH 7.0, threshold and rheobase are modulated by $\text{Na}_v1.7$ and $\text{Na}_v1.9$, which both channels are possibly up-regulated via G-protein signaling pathway of ASICs. These cause the neuronal excitability that will reach the threshold for triggering AP.

AP is driven by Na^+ influx that passes through $\text{Na}_v1.7$ and $\text{Na}_v1.8$ during the depolarization state. The pore of voltage-gated sodium channels (Na_v) consists of four domains (DI-DIV), which each domain comprises from six trans-membrane segments (S1-S6) (118). While S1-S4 segments functions as the voltage sensing domain (VSD), S5-S6 segments forms the pore module (PM) which S5 segment is linked to S4 segment by S4-S5 linker (119). After the neuronal depolarization, the S4 segment which has positive charge of arginine is activated by altering the electric field resulting in outward movement through the groove of S1-S3 segments to pull the S4-S5 linker that induced the conformation change of the intracellular side of S5-S6 segments to open the gate (119). Moreover, the pore is rapidly inactivated to Na^+ influx through isoleucine, phenylalanine, and methionine (IFM) motif of the interlinking Domain III and IV (DIII-DIV) that modulates the inactivation by moving to the intracellular pore for occlusion (120). Our findings showed that the height and overshoot of AP ($\text{AP}_{\text{height}}$ and $\text{AP}_{\text{overshoot}}$) were reduced after pH change from 7.4 to 7.0.

These results are corresponded with the study of Vilin et al (121) demonstrated that low pH decreases AP_{height} and $AP_{\text{overshoot}}$ together with the time to peak of AP, which is faster compared with physiological pH. The reason is that the extracellular protons electrostatically bound to the carboxylated outer ring of channel pore and protonate some residues of amino acid. This condition causes Na_v channel block before IFM motif folding to the intracellular pore (121, 122). Therefore, the extracellular proton in pH 7.0 would directly block the pore of Na_v channels that leads to acceleration of the fast inactivation.

AHP is shaped by large (big) conductance calcium-activated potassium (BK_{Ca}) channel and small conductance calcium-activated potassium (SK_{Ca}) channel (123, 124). These channels are activated by the intracellular calcium (Ca^{+}) ion that are elevated via voltage-gated calcium channel (Ca_v). Then, Ca_v allows extracellular Ca^{+} ions passing into neurons, and then inositol triphosphate (IP3) is activated that results in release of intracellular Ca^{+} from endoplasmic reticulum to cytoplasm (125). The augment depolarization by increase of intracellular Ca^{+} facilitates K^{+} efflux that contributes to AHP. However, SK_{Ca} channel has more effect on AHP development compared with BK_{Ca} channel, whereas BK_{Ca} channel contributes in repolarization phase of AP (126). Our results showed that the depth of AHP (AHP_{depth}) was reduced in pH 7.0. This reduction may be modulated by the extracellular proton, which protonates histidine residues of outer pore of SK_{Ca} channels that results in the conformation change of pore to block K^{+} efflux (127). Moreover, it was indicated that pro-inflammatory mediators including PGE_2 and serotonin can suppress the AHP amplitude (128, 129). Therefore, pH 7.0 may inhibit the AHP amplitude via SK_{Ca} channels. However, the duration of 50 % AHP_{depth} peak (AHP_{50}) was longer in pH 7.0 that may be caused from the long lasting open of potassium channels. It is known that potassium channels are opened as long as prolonged depolarization (105, 129). In our experiment, we changed physiological pH (pH 7.4) to pH 7.0 within 10 minutes, and then injected the depolarizing current to the neurons. The previous study of Waldmann et al (92) showed that prolonged pH change causes sustained currents indicating that some ASICs are opened as long as the activation by continuous low

pH. These may cause the neuronal depolarization, and may activate the other potassium channels.

Effect of pH 7.0 on the large-sized neurons

In contrast to the small-to-medium-sized neurons, the effect of pH 7.0 cannot change the neuronal excitability and AP shape of large-sized neurons.

As described above, the neuronal excitability and depolarization are regulated by ASICs, TASK-3, and TRESK. ASICs are expressed on the large-sized neurons, and low pH from 6.8 can activate these ASICs (11, 16, 18). Moreover, TASK-3 and TRESK are not expressed in the large-sized neurons (111, 130, 131). These evidences supports our results that pH 7.0 did not alter the neuronal excitability of large-sized neurons. The reason is that extracellular proton cannot activate ASICs on large-sized neurons, thus there are not any Na^+ influxes and K^+ accommodation inside neurons and then neurons are not depolarized. Moreover, our results also showed that AP shapes did not change in pH 7.0, because neuronal excitability was not altered.

Effect of CGRP in modulating pH 7.0 on the small-to-medium-sized neurons

In our experiment, pH 7.0 plus CGRP altered the excitability of small-to-medium-sized neurons that RMP was more negative. The AP shape was also changed that $\text{AP}_{\text{height}}$ and $\text{AP}_{\text{overshoot}}$ were decreased, while rising time of AP (AP_{RT}) was longer than control. Interestingly, $\text{AHP}_{\text{depth}}$ was increased. These results may be the secondary effect of CGRP that CGRP activates its receptor on satellite glia cells (SGCs) that released the pro-inflammatory mediators and activates the small-to-medium-sized neurons (22, 23, 132). The reason is that our primary culture was mixed-culture that consists of small to large diameter neurons and non-neuronal cells, including

SGCs. Moreover, our results in this condition were controversial with pH 7.0 condition, excepting AP_{height} and $AP_{\text{overshoot}}$.

As described above, RMP is modulated by the extracellular proton via ASICs activation that results in TASK-3 and TRESK inhibition. Our results demonstrated that RMP shifted to more negative when TG neurons were treated with CGRP in pH 7.0 condition. These results would possibly be affected by the pro-inflammatory cytokines that were released from SGCs. However, the mechanism of this modulation is unknown (22, 24).

Our results showed that AP_{height} and $AP_{\text{overshoot}}$ were reduced in the pH 7.0 plus CGRP condition. These reductions were similar to pH 7.0 condition that the extracellular proton blocked the pore of Na_V channels, which are direct effect of the extracellular proton (121). However, the rising time of AP (AP_{RT}) in our results was longer. This was because the secondary effect of CGRP may modulate the opening of gate of Na_V channels via unknown mechanism, while common Na_V channels was rapidly open in responding to depolarization (121).

AHP_{depth} is regulated by SK_{Ca} channels, and it is reduced by inhibition of the extracellular proton (127). However, in the pH 7.0 plus CGRP condition in our experiment, AHP_{depth} was increased that may be modulated by the secondary effect of CGRP that pro-inflammatory mediators may activate the small-to-medium-sized neurons to up-regulate the expression of SK_{Ca} channels or abolish the inhibition of the extracellular proton. However, the mechanism is unknown.

Thus, the secondary effect of CGRP via pro-inflammatory mediators of SGCs should be investigated in the future.

Effect of CGRP in modulating pH 7.0 on large-sized neurons

Our results indicated that CGRP modulated the excitability of large-sized neurons under pH 7.0, that the numbers of spike was increased and rheobase was reduced. These suggested that large-sized neurons expressed CGRP receptor (22, 25,

73). However, pH 7.0 cannot activate ASICs on the large-sized neurons as described above. Thus, these alterations may be directly caused from the activation of CGRP on its receptor.

Rheobase is a threshold current which is injected to neurons by commanding current to evoke AP. If the neurons are depolarized, the current that injected to the neurons is weakened. The neurons are depolarized by positive charge inside. Our results showed that rheobase was reduced in pH 7.0 plus CGRP conditions. The reason is that the activation of CGRP receptor produces protein kinase A and C (PKA and PKC) via G-protein signaling, that phosphorylates voltage-gated sodium channels (Na_v), including $\text{Na}_v1.6$ and $\text{Na}_v1.8$ (133, 134). Both $\text{Na}_v1.6$ and $\text{Na}_v1.8$ are expressed on the large-sized neurons (135, 136). In addition to rheobase, our findings showed that the number of spikes was increased that is consistent with the reduction of rheobase in pH 7.0 plus CGRP conditions. These results suggested that CGRP may directly affect the large-sized neurons via phosphorylation of voltage-gated sodium channels (Na_v) causing Na^+ influx and then AP is evoked.

The mechanism of CGRP activity

Figure 5.1 Illustration shows the modulation of CGRP on the excitability of the small-to-medium-sized neuron. CGRP may modulate the mechanism of the excitability via pro-inflammatory mediators from SGCs. The mechanism is unknown. There would be a signaling cascade that inhibits or activates or up-regulate the ion channels. These cascades are involved with the activation of the ASICs, that may inhibit the activation of TASK-3, TRESK, and SK_{Ca} (see dash arrow). These cascades may cause the hyperpolarization of neurons and enhances the depth of AHP.

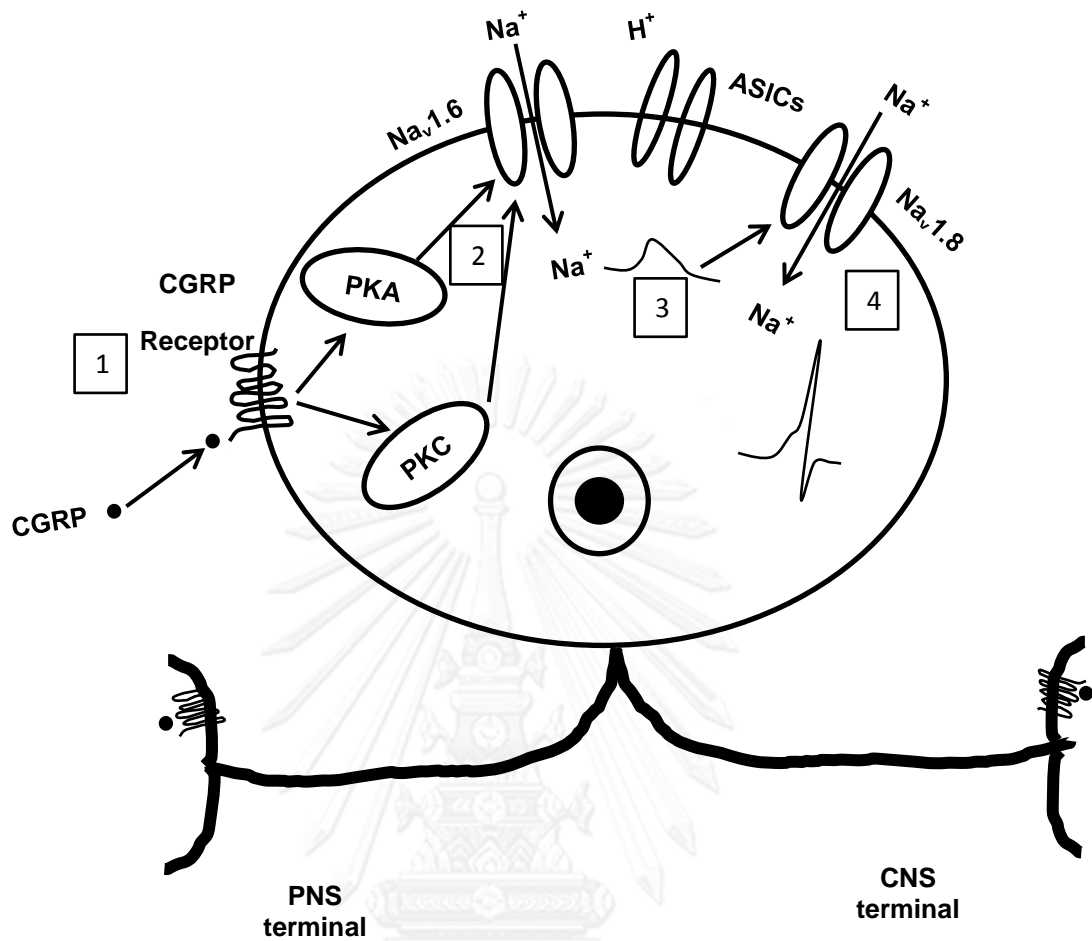

Figure 5.2 Illustration shows the modulation of CGRP on the excitability of large-sized neurons. The mechanism is initiated by CGRP as described below. First, CGRP activates its receptor causing up-regulation of PKA and PKC. Second, PKA and PKC may phosphorylate Na_v1.6 that leads to Na⁺ influx. Third, Na⁺ influx produces the neuronal depolarization. Fourth, the depolarization reaches the threshold of Na_v1.8 causing further Na⁺ influx passing into neurons and producing AP.

Limitations

This study investigated in the condition of pH 7.4 versus pH 7.0 and pH 7.4 plus CGRP versus pH 7.0 plus CGRP. There is not any information about pH 7.4 versus pH 7.4 plus CGRP and pH 7.0 versus pH 7.0 plus CGRP. This limitation may make us difficult to interpret the results about the mechanism of the secondary effect of CGRP.

Future study

This experiment was performed under the current-clamp whole cell recording technique to study the role of pH 7.0 and the modulation of CGRP on pH 7.0 in the small-to-medium-sized and large-sized neurons. The molecular basis and the voltage-clamp whole cell recording technique are insufficiency. Hence, the expression, intracellular signaling pathways, and properties of individual ion channel should be investigated in the future study. Moreover, the further study should repeat experiments for investigating the condition pH 7.4 versus pH 7.4 plus CGRP and pH 7.0 versus pH 7.0 plus CGRP.

CHAPTER VI

CONCLUSION

The present study demonstrated that low pH (pH 7.0) alter the excitability and AP shapes of the small-to-medium-sized neurons via ASICs and other ion channels, while low pH did not alter the properties of the large-sized neurons. Moreover, CGRP has an effect on the properties of the large-sized neurons, whereas CGRP may modulate the effect of pH 7.0 on the small-to-medium-sized neurons via activation of the SGCs that may be the secondary effect of CGRP. However, the mechanism of the secondary effect of CGRP is unknown. These results indicated that CGRP has a direct effect on the large-sized neurons, while performed indirect effect on ASICs and other ion channels of the small-to-medium-sized neurons via the activation of the SGCs.
