

CHAPTER 4

DESCRIPTION OF THE RESEARCH AREA

4.1. Geography and Geological Setting

The research area is located in the central part of the Lower Central Plain of Thailand, expanding from 656000 UTM (Northing) to 668000 UTM (Northing) to the north and from 1556000 UTM (Easting) to 1574000 (Easting) to the east (see Figure 4.1). Based on the administration map, the research area belongs to Phra Nakhon Si Ayuthaya and Pathum Thani provinces. The length in the north-south direction is roughly 18 km and west-east direction is 12 km, comprising the entire area of 216 km². The topography is relatively flat, with gradually decreasing elevation from the north to the south. The variation of elevation ranges from 1.8 to 6 meters above mean sea level (MSL) (see Figure 4.2)

The central Plain of Thailand has been subjected to three major kinds of depositional environments namely the alluvial fan type, the flood plain or fluviatile type, and deltaic-marine type of environment (Goh, 1975). According to Piancharoen & Chuamthaisong (1976), the lower central plain is a geological depression filled with alluvial and deltaic sediments with occasional shallow sea sedimentation. The depth varies probably from hundreds to thousands of meters. The basement is overlain by a thick sequence of unconsolidated, deltaic, marine and alluvial sediments of Tertiary and Quaternary origin, which in turn underlay a stratum of highly compressible soft Bangkok clay of Holocene age. The sedimentary deposits in the Lower Central Plain vary widely in the type of sediment, thickness and distribution. In the central part of the Basin, interbeds of sand, clay and gravels hundreds of meters thick occur, whereas toward the edges only thin veneers of sediments lie on top of shallow bedrock (AIT, 1981).

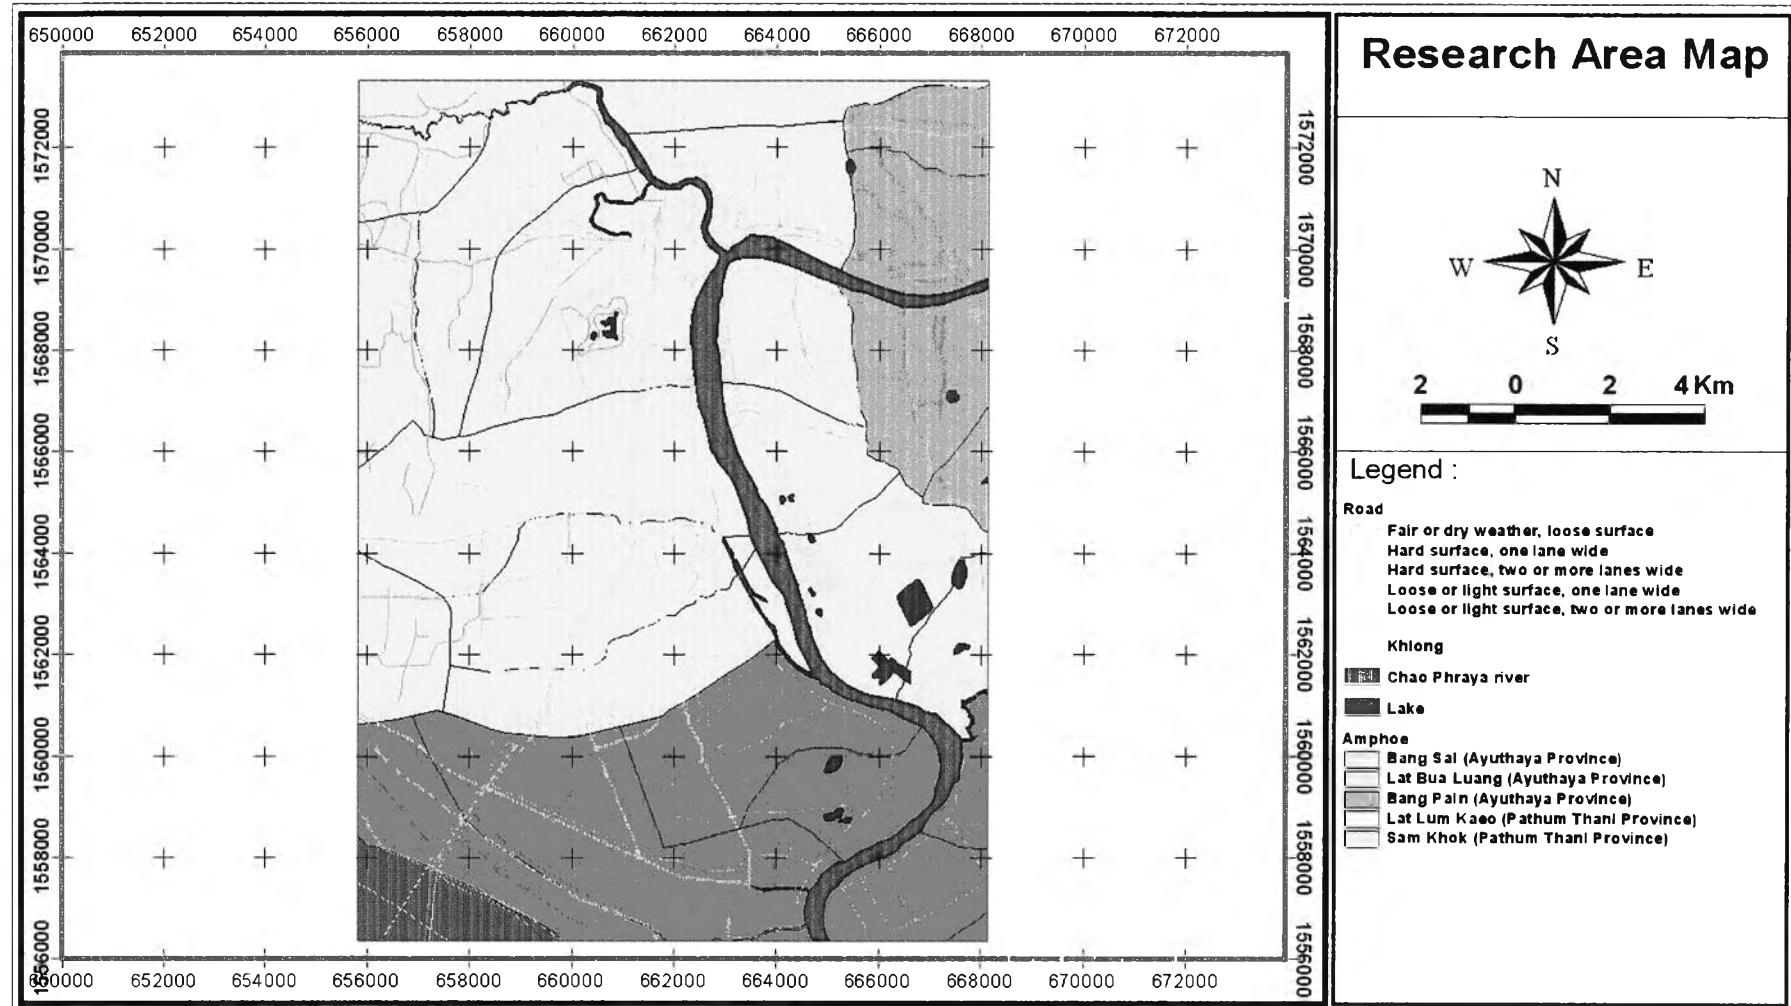

Figure 4.1. Research area map.

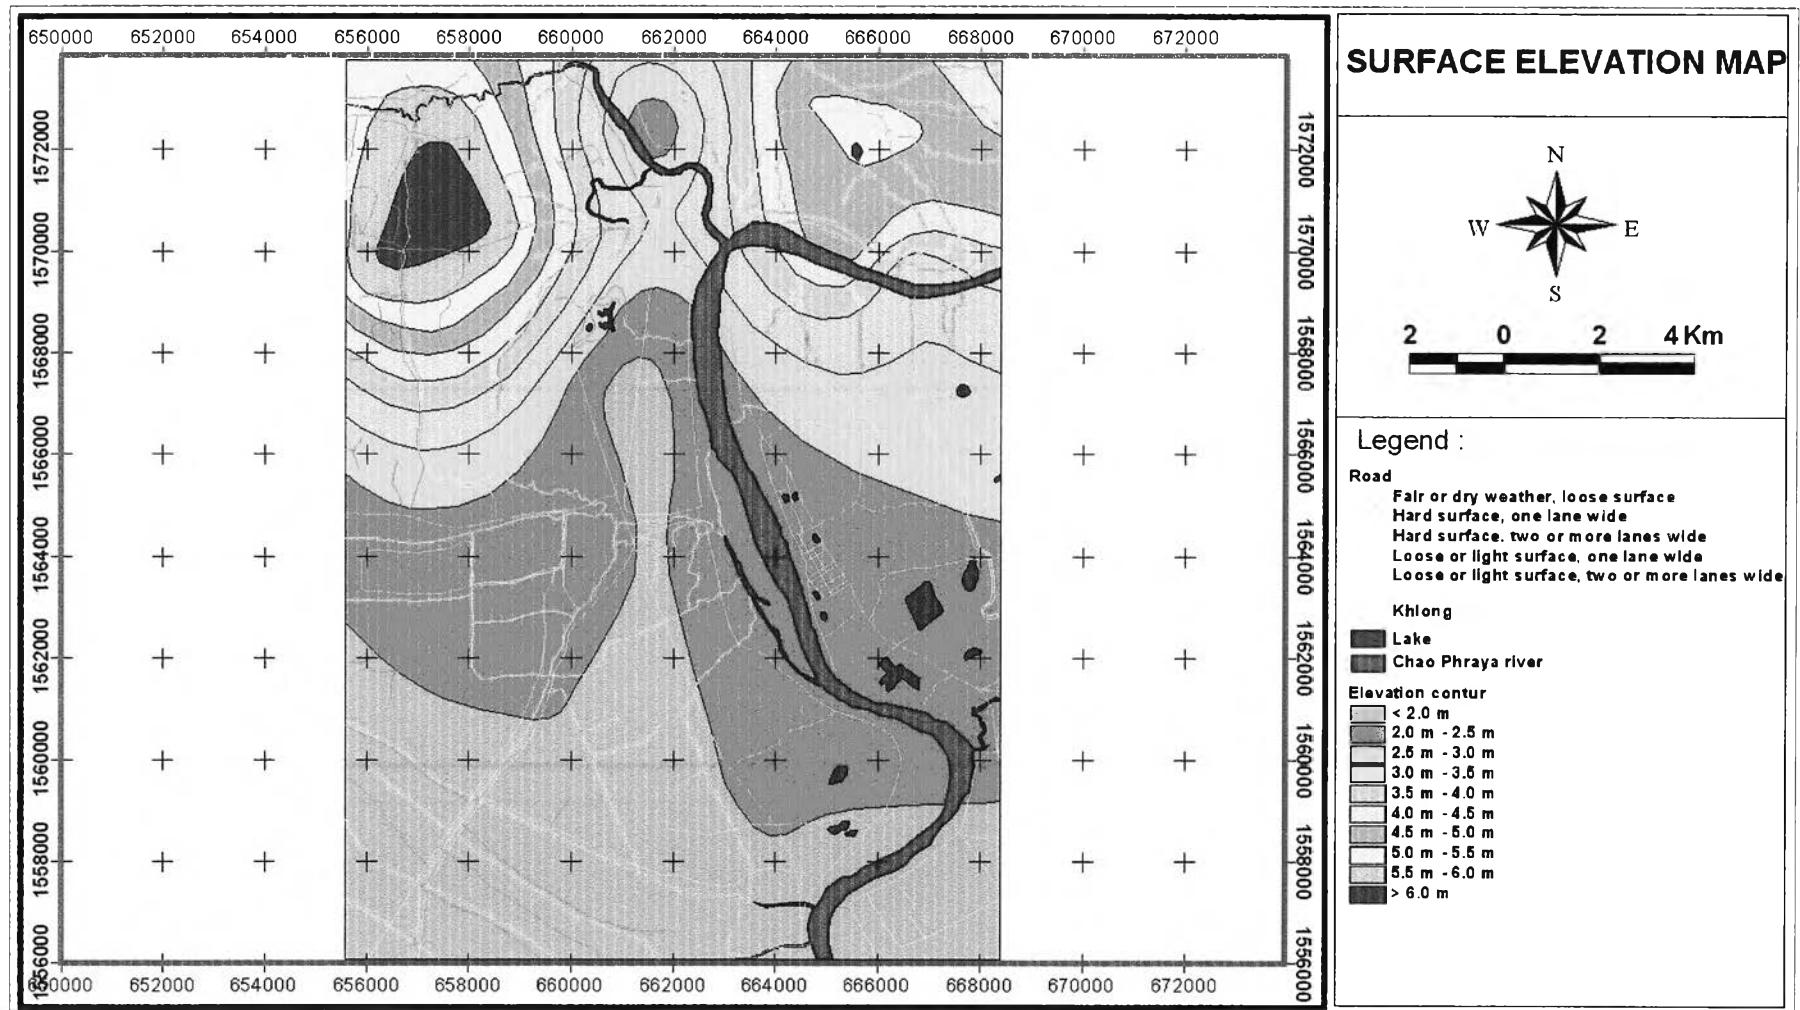

Figure 4.2. Surface elevation map.

The uppermost layers of the stratigraphic column, in the research area, are known under the term Bangkok clay, which consists of three units, i.e. weathered clay, soft clay, stiff clay (Moh, 1969). The weathered clay, of 1 or 2 meters thick, is topmost. The Bangkok soft clay can be up to an average depth of 15 meters. It is deposited on an erosion surface of stiff clay, which directly overlies the first sand layer. The most abundant clay mineral in the Bangkok soft clay is kaolinite (47 to 64%), montmorillonite (20 to 43%) and illite (to 20%).

The wells log data in the area show that the geological conditions consist of interbeds between clay, sand, gravel, sandy clay, clayey sand, gravelly sand (see Figure 3.3). Figures 3.4 and 3.5 show the cross section and fence diagram based on the available data in the research area. The details of all wells log in the research area are attached in Appendix 1.

4.2. Hydrogeology and Aquifer System

Extracted from the hydrogeologic map of Lower Central Plain of Thailand (Charoen Piancharoen and Somsak Isarangkula, 1974), the research area consists of alluvial deposit material with series of productive aquifer. Defined by the alternating sequence of clay and sand and gravel layers, the aquifer system can be divided into 8 layers at approximately 50 meters interval namely Bangkok aquifer (BK), Phra Padaeng aquifer (PD), Nakhon Luang aquifer (NL), Nonthaburi aquifer (NB), Sam Khok aquifer (SK), Phaya Thai aquifer (PT), Thon Buri aquifer (TB) and Pak Nam aquifer (PN). The piezometric head of Nakhon Luang aquifer ranges from 20 to 30 meters below sea level. The direction of groundwater flow is come from north-west direction.

The ground surface of the research area is entirely underlain by blue to gray marine clay, 15 m to 30 m thickness, known as the Bangkok clay (Muktabhant et.al., 1996). In general, the unconsolidated and semi-consolidated sediments overlying the basement have a total thickness of about 400 m to more than 1,800 m. From a detailed study of logs of groundwater wells, the Department Mineral Resources identified and named eight (8) aquifers within 550 meters depths (Table 3.1). These aquifers consist mainly of sand and gravel separated by clay beds.

In consideration of aquifer productivity, the water in the first aquifer (Bangkok aquifer (BK), 50 m zone) is not potable due to high salinity. The second aquifer (Phra Pradaeng aquifer (PD), 100 m zone), the third aquifer (Nakhon Luang aquifer (NL), 150 m zone) and fourth aquifer (Nonthaburi aquifer (NB), 200 m zone) are very productive. Most wells in Bangkok pump water from these three aquifers. The fifth aquifer (Sam Khok aquifer (SK), 300 m zone) and the sixth aquifer (Phaya Thai aquifer (PT), 350 m zone) are increasingly being developed in Pathum Thani province northwest of Bangkok. The seventh aquifer (Thon Buri aquifer (TB), 450 m zone) and the last aquifer (Pak Nam aquifer (PN), 550 m zone) are used for industrial purpose in the south and southwest areas of Bangkok where there are no alternative overlying potential aquifers. They are, however, too deep for domestic wells (Ramnarong & Buapeng, 1991).

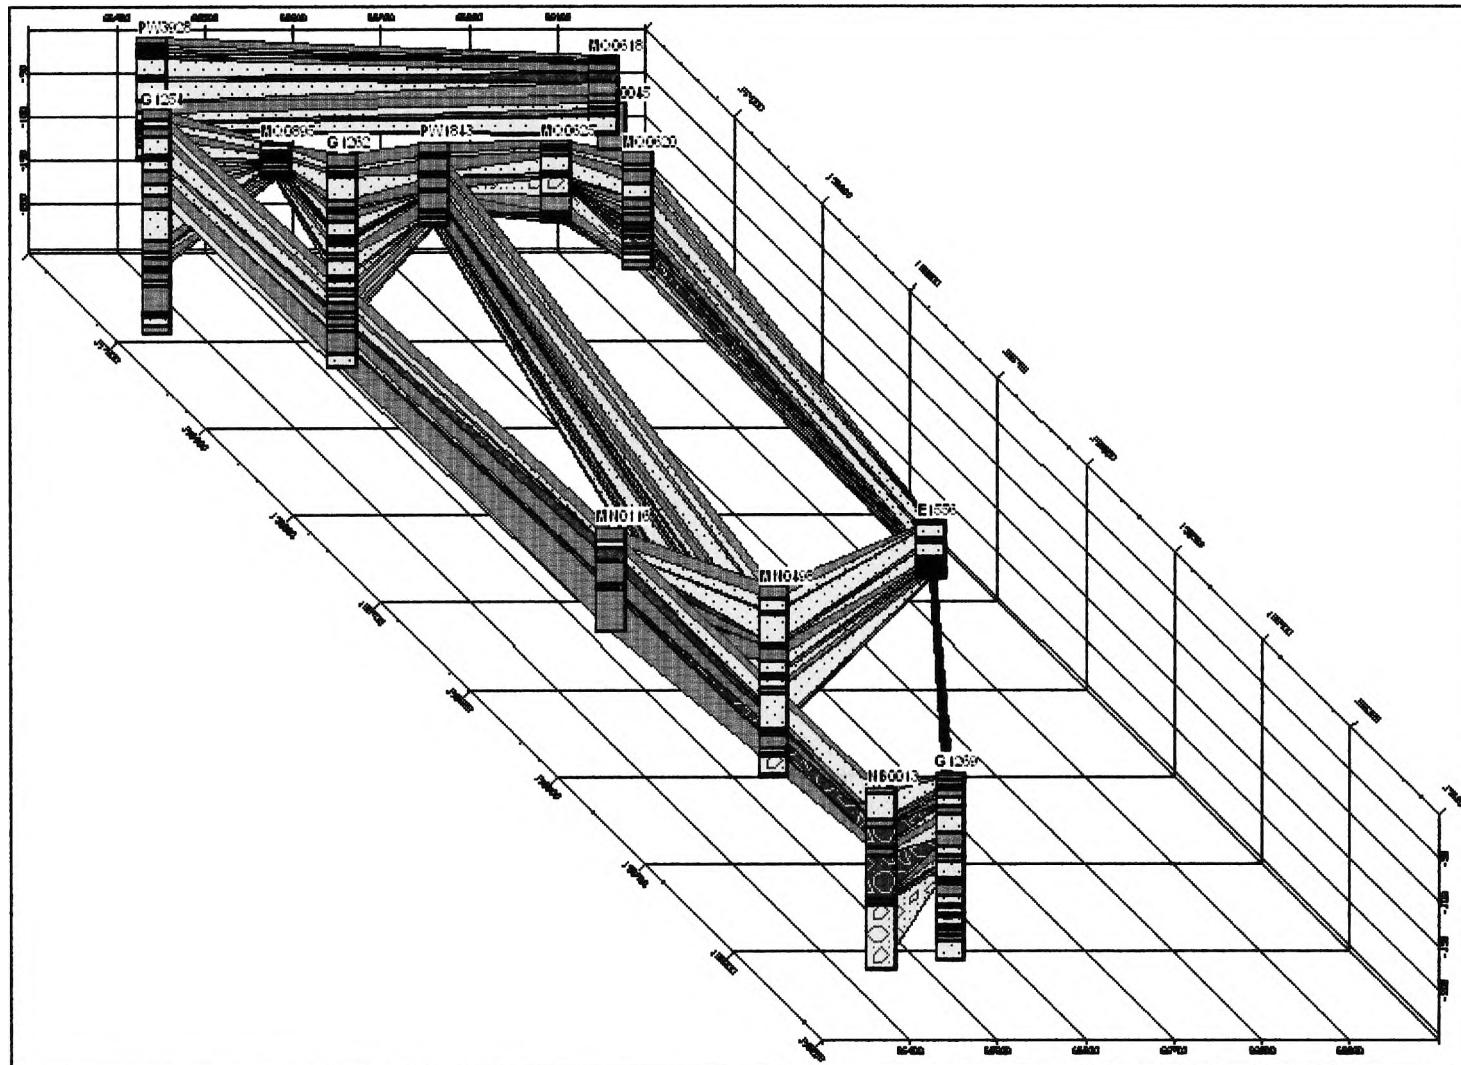

Figure 4.5. Fence diagram.

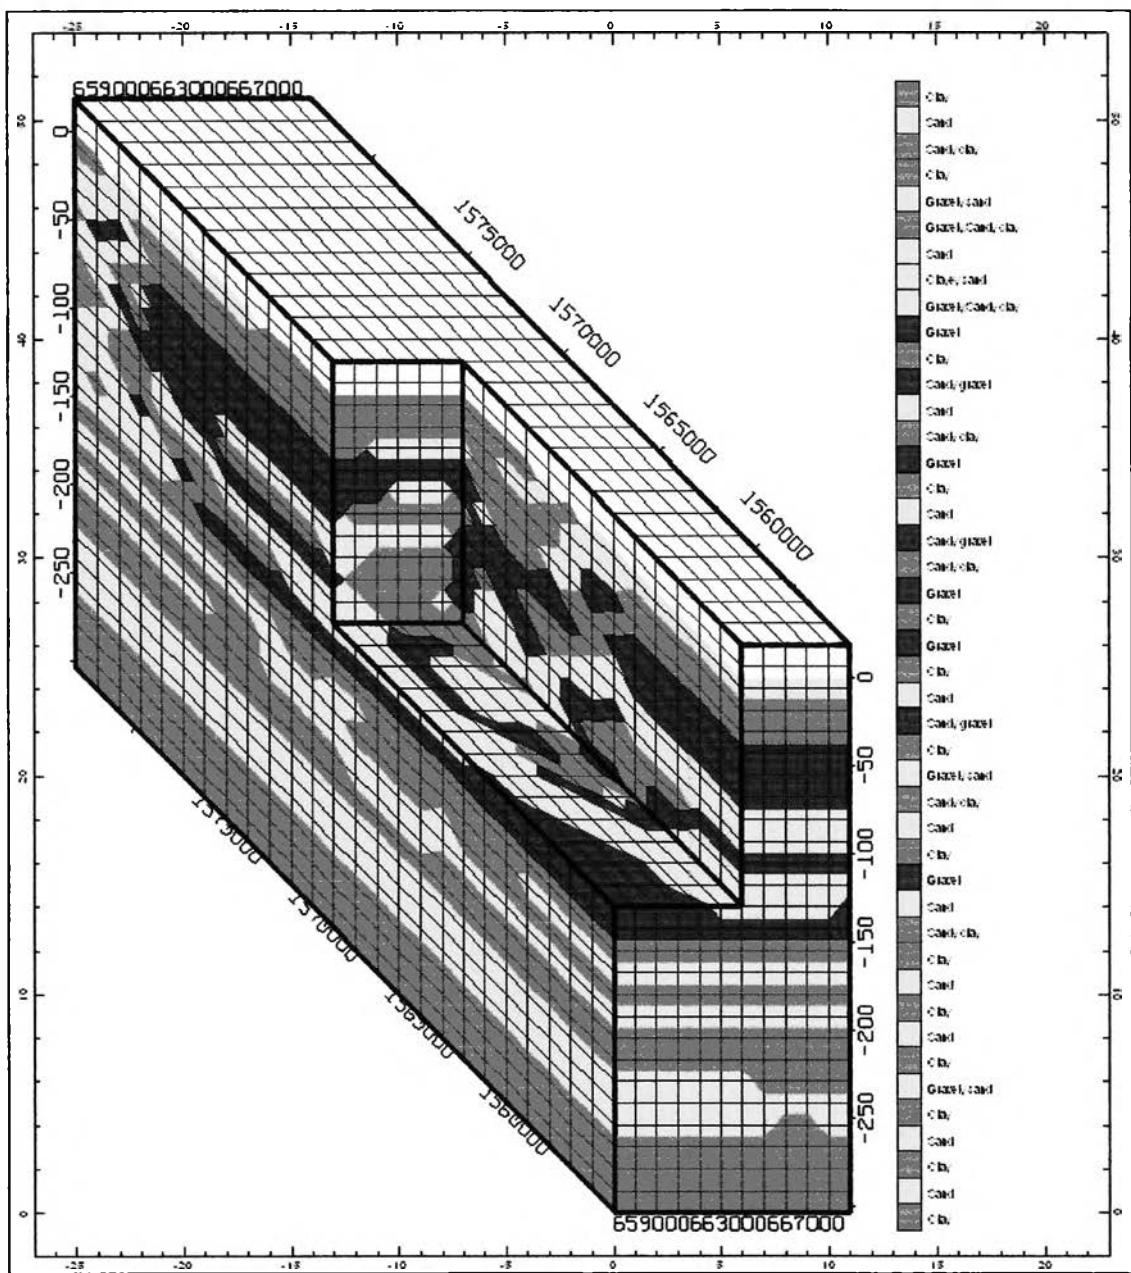

Figure 4.6. Stratigraphic modeling.

Table 4.1. Stratigraphic section of Bangkok and adjacent areas and their water-bearing properties (after Chiamthaisong, 1980).

Age	Aquifer	Thickness	Lithology	Water-bearing Properties
Late-Pleistocene to Recent	1 Bangkok (50 m zone)	± 50	Topmost clay is generally dark gray to black, limonitic lateritic in the upper portion. Coarse sand, gravel and pebble are sub angular to rounded, moderately to well sorted, composed mostly various types of fragment.	Yields considerable quantity of water of poor quality, brackish to salty and highly mineralized. Normally not developed for groundwater resource.
	2 Phra Pradaeng (100 m zone)	± 50	Separated from the Bangkok aquifer by a dark stiff clay bed. Gravel-sand is characteristically white to pale gray, sub rounded to rounded, fairly well sorted, composed mostly of quartz, chert and other rock fragment, with carbonized woods and peats at the lower part. Clay lenses interbed in places.	Yields water of good quality only in the south and southwest of Bangkok, in other areas the aquifer yields brackish to salty water.
Lower to Middle Pleistocene?	3 Nakhon Luang (150 m zone)	± 50	Over lied by thick and hard clay bed. Sand-gravel layer, which from the aquifer are rather thick (10-15 m). Fragments, mostly quartz, feldspar and quartzite; are sub angular to sub rounded, moderately to well sorted. Interbedding clays are whitish to yellowish to grayish brown, sandy and limonitic, non-plastic.	Has been heavily developed for public water supply. Yields 100 – 250 m ³ /hr of water of excellent quality. Only in the south and southwest of Bangkok wells yield salty water due to salt-water intrusion into the aquifer.
	4 Nonthaburi (200 m zone)	± 50	General characteristics of the formation are the same as the Nakhon Luang aquifer. It is consisted of rather uniform thick sands and gravels with minor sandy clay lenses. The formation can be divided into three units separated by leaky clay layers.	It is one of the most productive aquifers, which yield up to 200 m ³ /hr of water of excellent quality. The water has been extensively used for bottled drinking water and brewerage as well as domestic supplies.
	5 Sam Khok (300 m zone)	± 100	The formation is consisted of sand, gravel and clay. Sand-gravel is yellowish brown to dirty brown, but may grade to white color, medium to very coarse grained, angular to sub rounded, fairly well sorted, feldspathic, calcareous due to limestone fragment in places; with interlayering clays. Both sand-gravel and clay beds are moderately to highly compacted.	Yields slightly less than those of the Nakhon Luang and Nonthaburi aquifers. Normally penetrated by production wells in Northern Bangkok since shallower aquifer yield water of higher iron content.
	6 Phaya Thai (350 m zone)	± 50	Consisted of sand gravel and clay. Sand and gravel are dirty brown, angular, sizes ranged from medium sand to gravel size, poorly to fairly well sorted; quartz and chert being major composition. Clay is brown, compact, calcareous and lateritic.	Wells drilled in Central and Southern Bangkok yield brackish to salty water while those in Northern Bangkok produce fresh water. The aquifer is generally not popular due to its greater depth.
	7 Thon Buri (450 m zone)	± 100	Separated from the upper formation by hard and compact clay. Sand and gravel beds are usually alternated layering with clay beds. Color is generally gray to brownish gray to occasional white sand layers.	No production wells ever constructed, but the packer tests of several test holes indicate that the water is fresh to slightly brackish or mineralized in places. The aquifer is not so productive as the above aquifers due to the presence of clay in many horizons.
	8 Pak Nam (550-m zone)	± 100	Separated from the upper formation by leaky clay to sandy clay layer. Sand and gravel beds, generally thicker than that of Thon Buri aquifer, are white to gray and well sorted. The clay is generally very compact, olive gray to dark gray, with carbonaceous matters.	The aquifer is very permeable and yields a considerable quantity of water of good quality. Water temperature is as high as 43 °C. However, too deep to reach by domestic wells, except in areas where there is no alternative potential aquifer; i.e. the Southern Bangkok.

The vertical spreading of Bangkok aquifer is from 30 to 60 meters, and Phra Pradaeng aquifer is from 60 to 120 meters with productive aquifer at 90 to 100 meters depth. However, the Phra Pradaeng aquifer can be sub-divided into 3 to 4 layers confined by clay layers. Nakhon Luang aquifer located at 120 to 180 meters with productive aquifer at 140 to 150 meters. It can be sub-divided also into 4 to 5 layers of aquifer. Nonthaburi aquifer located at 180 to 280 meters with productive aquifer at 200 to 250 meters depth. Sam Khok Aquifer located at 280 to 360 meters depth with productive aquifer at 330 to 350 meters. Phaya Thai aquifer located at 360 to 430 meters depth (productive aquifer at 400 meters), Thon Buri aquifer located at 430 to 480 meters depth (with productive aquifer at 450 meters), Pak Nam aquifer located at 480 to 600 meters depth with productive aquifer at 550 meter (JICA, 1995).

There is a big variation of groundwater table in each aquifer. Throughout the years, not only there is a change in groundwater level, but also the flow direction as well. Each year, it has changing in the depth and also the flow direction. The groundwater level of Phra Padaeng aquifer varied from 12 to 22 meters below SWL. Nakhon Luang aquifer has a groundwater level depth around 21 to 27.5 meters below SWL. Nonthaburi aquifer has a depth of groundwater level start from 23.6 to 27.6 meters below SWL. Basically, the flow of groundwater is come from the north-west direction in the research area, but there is a small variation among different aquifer layers (see Figure 4.7) .

The permeability of Bangkok aquifer is 3.4 m/hr with storage coefficient of 1×10^{-4} . The permeability of Phra Pradaeng aquifer ranges from 2.4 to 3.74 m/hr with storage coefficient from 1×10^{-4} to 2×10^{-4} , and the permeability of Nakhon Luang aquifer ranges from 2.2 to 3.45 m/hr with storage coefficient from 1×10^{-4} to 3.4×10^{-3} (AIT, 1981). Based on the pumping test on Nonthaburi aquifer from wells DR132 the hydraulic conductivity obtained from theis method is 27.22 m/day with storage coefficient of 1.29×10^{-4} . The pumping well DR133 yielded a result slightly different from DR 132 with the hydraulic conductivity value of 21.312 m/day and storage coefficient of 1.26×10^{-4} . The detail analysis and pumping test data are attached in Appendix 2. The results of pumping test analysis are summarized in Table 4.2. Table 4.3. summaris of aquifers and clays properties from reffered sources.

Table 4.2. Pumping test analysis.

Pump. Test	Well Function	Well Code	Method of Analysis	Hydraulic conductivity (m/day)	Storage coefficient (1/m)
1	Pumping well	DR 132 PSA 54	Recovery	25.92

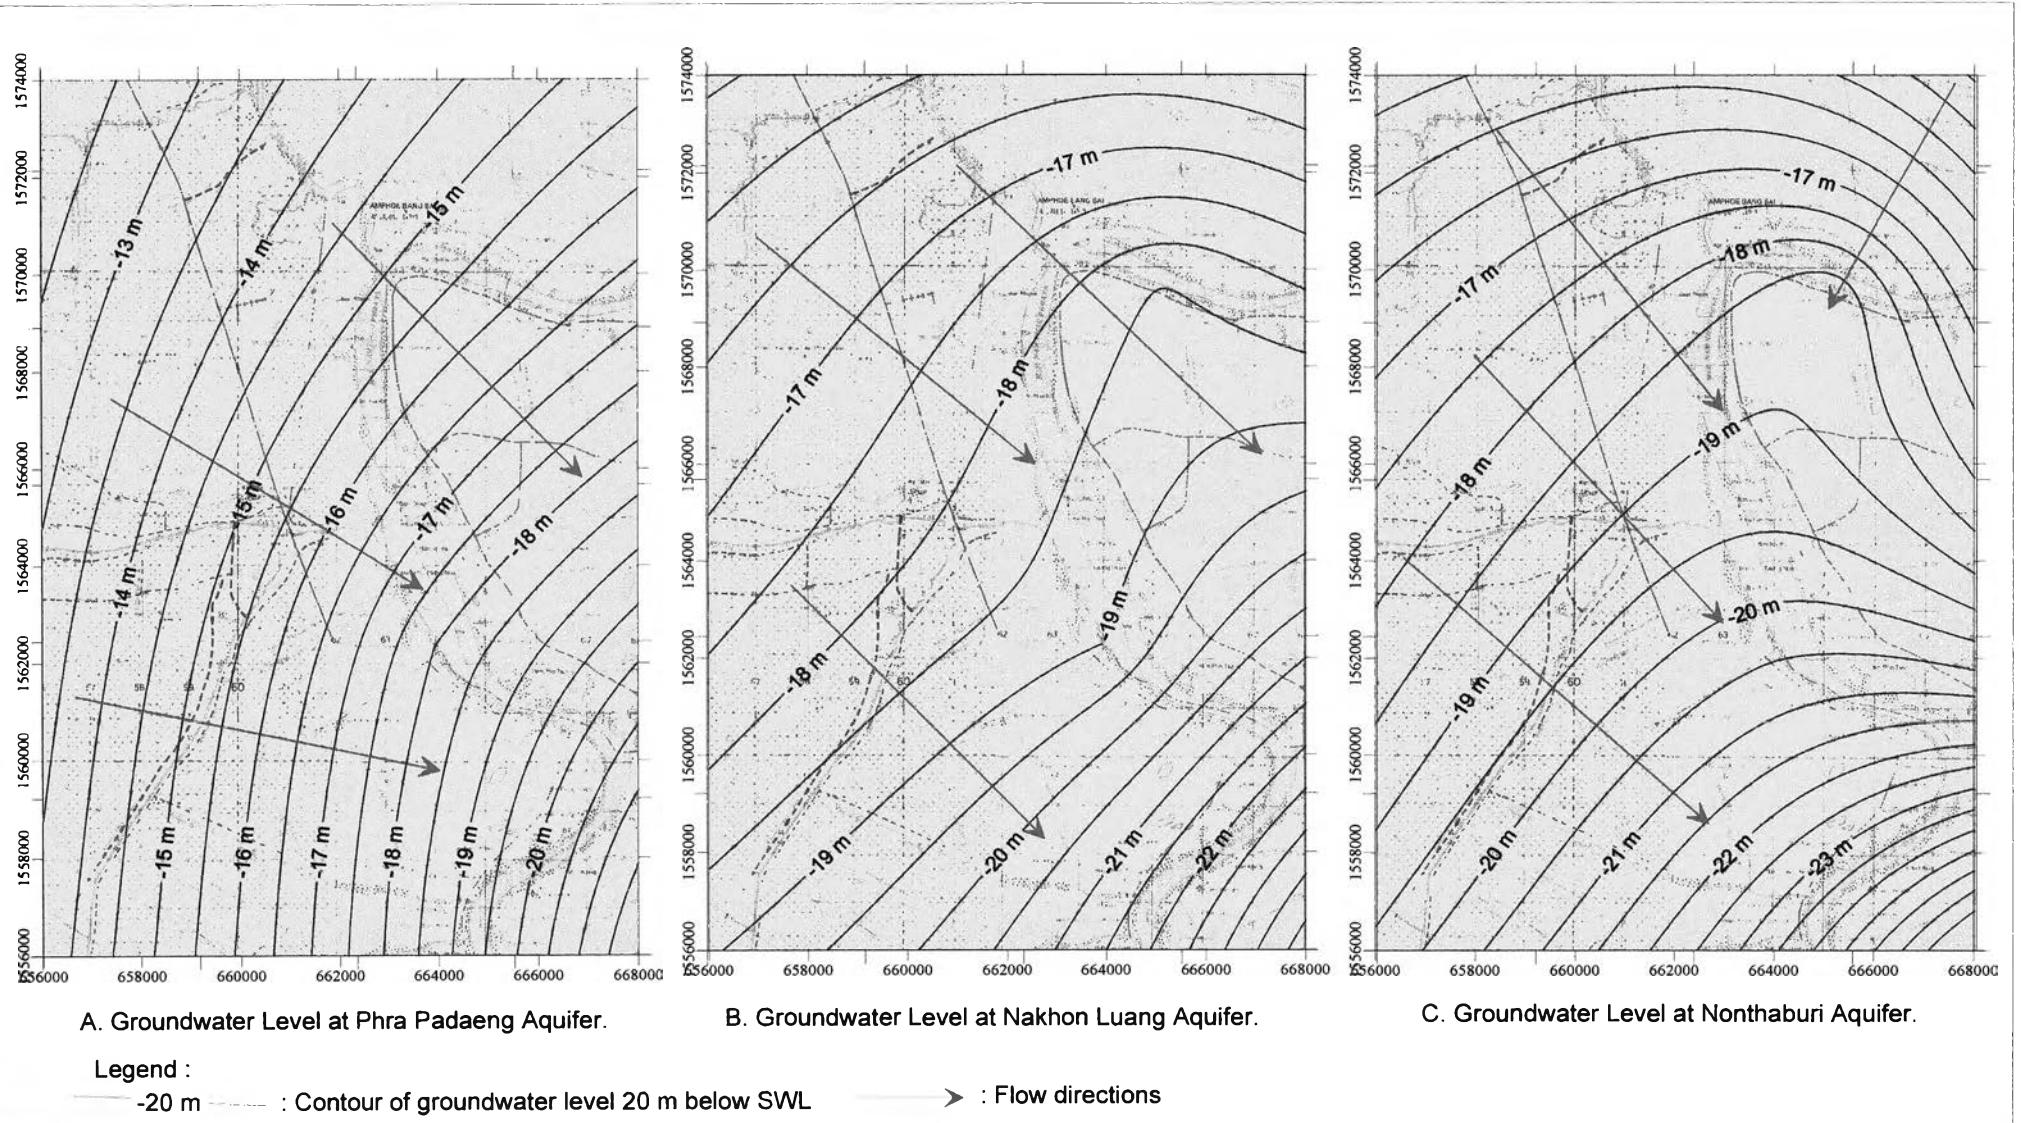

Figure 4.7. Groundwater Level in The Research Area.

4.3. Hydrology

The Chao Phraya river basin occupies most of the northern region and the Central Plain of Thailand. The total drainage area of the Chao Phraya river basin is about 160,000 km². The whole drainage area is generally divided into the Upper Chao Phraya river basin and The Lower Chao Phraya river basin. The outlet of the Upper Basin is located at Nakhon Sawan at which the rivers of the northern region Ping, Wang, Yom and Nan emerge to become the Chao Phraya river. The drainage areas of the Upper and Lower Chao Phraya river basins are 105,929 and 53,417 km², respectively (AIT, 1982)

As shown Figure 3.6, the average discharge of the Chao Phraya river downstream of the confluence of the Ping and Nan rivers at station C.2 in Nakhon Sawan is 683.62 m³/sec. The drainage area above this station is 111,435 km². About 100 km downstream from Nakhon Sawan near Chai Nat province. The Chao Phraya dam was constructed to divert the river flow to irrigate an area of about 97.9 km² located downstream along both sides of the Chao Phraya river. From a drainage area of 120,693 km², the flow of the Chao Phraya river downstream of this dam at station C.13 has decreased to 336.10 m³/sec.

On downstream of Chai Nat province, many effluent branches off from the main river such as Suphan, Noi and Lop Buri rivers. The discharge of the Chao Phraya river before it reaches the city of Ayuthaya as observed at station C.7A is averages at 358.02 m³/sec.

At the city of Ayuthaya, where the Chao Phraya river joins with fifth tributary on the east, the Pasak river. From there, the river enters the research area and meander as a single channel southwards until it meets the Gulf of Thailand. The study area is located on west side of the Chao Phraya river.

The lower stretch of the Chao Phraya river is affected by ocean tides, by which extends up to Bang Sai district and Rama IV Dam in the Pasak river (JICA, 1987).

As shown in Figure 3.6 river flow fluctuates sharply according to the season changed. For instance, the discharge of the Chao Phraya river at station C.7A varies from 495.8 to 835.3. m³/sec in the period from January to August with a minimum of 354.1 m³/sec in February, while the discharge in the period of September to December

exceeds 1,000 m³/sec with a maximum of 2,789.7 m³/sec in October. The capacity of the river is only 1,500 m³/sec near Ayuthaya and the excess water will overflow and flood the low-lying area including the research area from September to November. As mentioned above, the gradient of the river ranges only from 1/10,000 to 1/50,000 for its lower course.

Tables 4.4 and 4.5 show the groundwater level head in the Chao Phraya river at Bang Sai (Ayuthaya) and Muang (Pathum Thani) stations. The highest of level occurs in the October and November, and the lowest level in the February and March.

Not only the Chao Phraya river serves as a main river in the research area, but also there are many canals that called Khlong criss-cross the study area. Some khlongs are intermittent but almost all of them are perennial with mouth in the Chao Phraya river. They also have five lakes in the research area. The biggest lake located in the middle of research area with covering area of 0.09 km².

Water qualities in Chao Phraya river are showed in Table 4.6, BOD values from the upstream, middle and downstream are higher than Water Quality Standard values of class 2, class 3, and class 4, respectively, while most parameters were still in the range of Water Quality Standard class 3 (Monchan Maketon at all, 2003). The calculated Water Quality Index (WQI) is shown in Table 4.7, it is relatively high because Fecal-coliform bacteria (FCB) value is not included in the calculation. The indices indicate that the water qualities in the upstream and the middle are very good to fair instead of fair to poor, but the downstream qualities are poor at all sites.

4.4. Climate

4.4.1. Rainfall

The research area is located in the monsoonal region, which has a distinct dry season and a flood season caused by monsoonal rains. Over the Lower Central Plain, most of the rain is caused by the regular south-west monsoon winds but a smaller portion falls in the form of very intense torrential showers resulting from tropical storms. The average frequency of tropical storms entering Thailand is approximately two storms per year, which generally occur during the months of May through December.

With its flat topography, very little variation exists in the rainfall regime within the research area, therefore, the monthly and annual rainfall data for Phra Nakhon Si Ayuthaya province be considered representative for the entire research area. Based on 10 years recorded data from 1993 to 2002 in the Tha Ruat station, the average monthly rainfall in the research area can be calculated. The average of annual rainfall is 1066.64 mm, with the highest rainfall occurs in 1999 (1,420.30 mm) and lowest in the 1997 (741.10 mm). The mean monthly rainfall value varies from 8.33 mm (January) to 223.70 mm (September). About 86 % of the rainfall occurs from May to October, with September generally as the month of highest rainfall. The period from November to March is distinctively dry. The details of mean monthly rainfall in the research area are summarized in Table 4.8.

4.4.2. Temperature, relative humidity, evaporation and evapotranspiration

The mean monthly variation of temperature and relative humidity are measured at Ayuthaya Agromet station. The station is located in Tha Rua, Bang Pain, Ayuthaya outside the study area in the north around 25 km. The mean monthly temperature varies from 20.8 °C (March) to 38.88 °C (April). The data indicates that, on the average, monthly temperature ranges from a minimum of 26.04 °C (December) to a maximum of 30.79 °C (April). The coldest months are December and January while the warmest months are March and April.

The monthly average relative humidity ranges from a maximum of 97.7% to a minimum of 16.3%. The months of April, May and November record the highest relative

humidity readings, while the months of January, February and March record the lowest. Mean annual relative humidity is recorded at 64.25%.

In Ayuthaya, mean monthly evaporation varies from a minimum of 112.52 mm in September to a maximum of 180.07 mm in April. The maximum evaporation in ten years period is 2,000.51 mm occurred in 1993 and the minimum is 1,661.21 mm occurred in 1999. Estimated annual mean is set at 1,776.91 mm. With the above temperature and humidity conditions, evaporation is considered high in the study area.

The evapotranspiration data is calculated using Reference Evapotranspiration Calculator (REF-ET) software. The input data are latitude, elevation, air temperature, humidity, wind speed, sunshine hour and solar radiation. The monthly average data in ten years (1993-2002) from the measurement in the field is used as an input into the REF-ET software. REF-ET software calculates the daily evapotranspiration, by which total evaporation in month is equal to daily evapotranspiration multiply by amount of day in that month. The result shows the maximum evapotranspiration of 194.80 mm (see Table 4.9.) occurred in April and minimum of 136.25 mm. occurred in September. The comparison graph of rainfall, evaporation and evapotranspiration is showed in Figure. 4.9.

Graph of Rainfall, Evaporation and Evapotranspiration

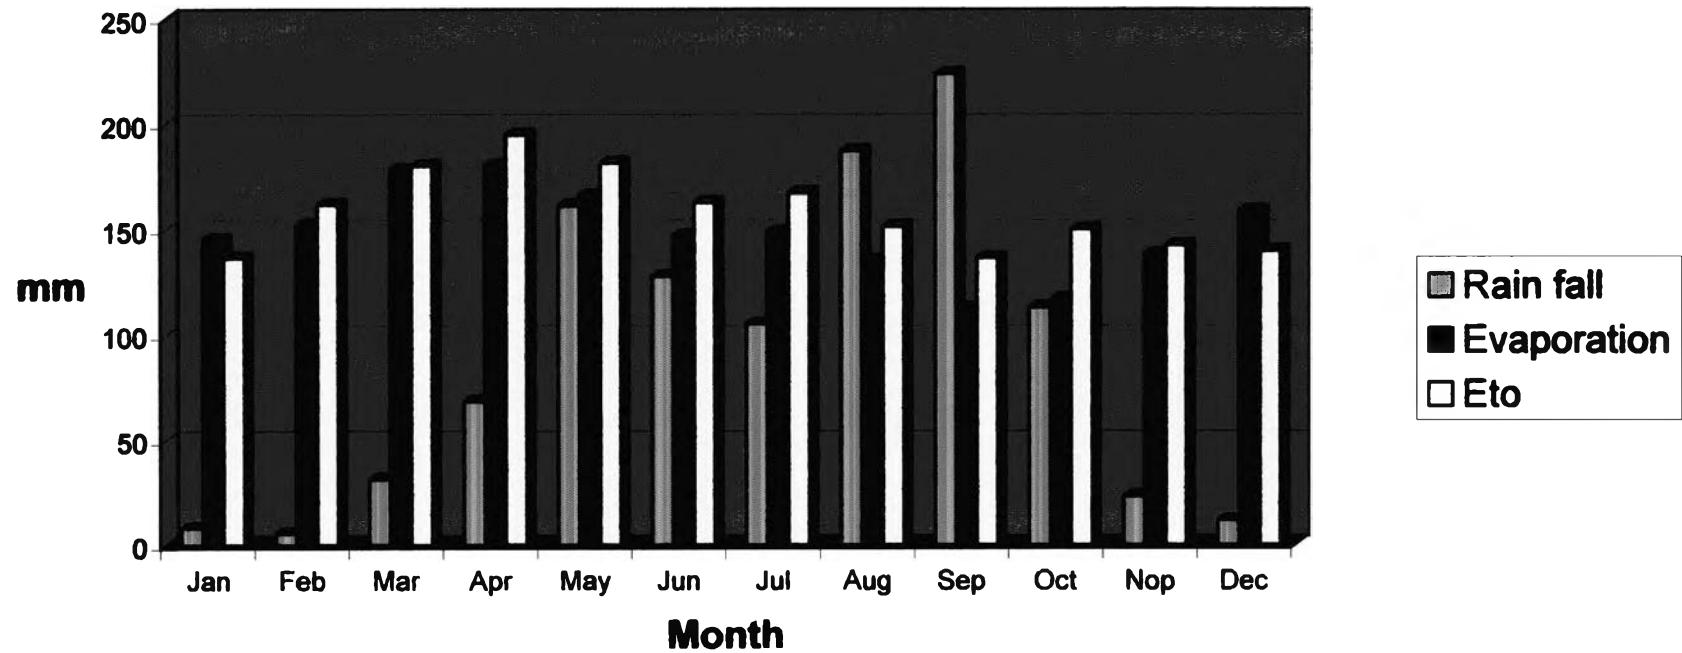

Figure 4.9. Comparison graph of rainfall, evaporation and evapotranspiration from 1993 to 2003.

4.5. Land Use and Soils

The newest 1: 1,000,000 scale land use map is produced by Land Development Department in 1998 (see Figure 4.10). The units are broadcasted paddy field 80%, field crops 3 %, orchard 4 %, horticulture 5%, swidden cultivation 2 %, pasture and farm house 2 %, lowland and village 2%, allocated land project 1%, industrial estate 0.5%, water body 2% and others 1.5% of the land area.

Basically, land quality in the research area is good and belongs to Class I category (according to The soil resources of Thailand, 1996). These are prime land highly productive soil, with few management-related constraints. Soil temperature and moisture conditions are ideal for annual crops. Soil management consists largely of sensible conservation practices to minimize erosion, appropriate fertilization, and use of the best available plant materials. Risk to sustainable grain crop production is generally less than 20%.

Based on the Soil Survey Division 1972 and 1976, the research area consists of alluvial soil type (National 1 Classification). Using the USDA-1970 classification of soil, it can be divided into typic tropaquepts, sulfic tropaquepts, typic haplaquolls, aeric tropaquepts and suffice tropaquepts. The spreading of soil type is dominated by typic tropaquepts around 40% from the total area. Suffice tropaquepts type can be found around Chao Phraya river and in southern part of the research area. The details of soil type in the research area are shown in Figure 4.10 and Table 4.11.

4.6. Groundwater Use

The groundwater use from the research area is estimated from the DMR recorded data. Private wells are those well registered with DMR for water rights, while Public Wells are those wells constructed or managed (or both) by Department of Mineral Resources, Metropolitan Waterworks Authority (MWA), Provincial Waterworks Authority (PWA), Accelerated Rural Development Office (ARDO) and Industrial Estates Authority Thailand (IEAT). Public wells are usually not registered with DMR for water rights.

The groundwater pumpage estimations basically relies on the Groundwater Database System, especially on the well inventory database system which stores all the different well inventories collected from the mentioned agencies. These well inventories contain 118 private wells, 14 public wells and 6 groundwater observation wells.

Table 4.12 and Figure 4.10 show the distribution of the inventoried private wells, public wells and observation wells by Changwat, by aquifer and by type of user. About 54 of the private wells are located in Pathum Thani province and 84 wells in Phra Nakhon Si Ayuthaya province, with more than 35% are extracted water from Nakhon Luang aquifer. Most of the public wells are located in Phra Nakhon Si Ayuthay province and are close to the Chao Phraya river. Note that the well screen position or the well depth is used to determine the aquifer from which a well is withdrawing groundwater. In circumstance that there is no recorded of screen position of groundwater wells, the produced aquifer is assumed from the closest wells and depth of drilling. Aquifers are identified using isopach of the three aquifers units. Nonthaburi aquifer is the most productive aquifer in the research area and the second is Nakhon Luang aquifer.

Based on the analysis of elements from samples of groundwater in the research area and its vicinity, they reveal that the water quality is still acceptable for drinking purpose, but some of them have content values higher than the standard for drinking water requirements. Therefore, the pumped groundwater must be treated before use it. The details of chemical analysis of groundwater are summarized in Table 3.13.
