Jirayu Kammarabutr : DRUG RESISTANCE MECHANISM OF NS3/4A PROTEASE AND IDENTIFICATION OF POTENT COMPOUNDS INHIBITING REVERSE TRANSCRIPTASE OF HEPATITIS VIRUS. Advisor: Asst. Prof. THANYADA RUNGROT MONGKOL, Ph.D.

Viral Hepatitis has become a public health concern which caused 1.34 million deaths in 2015 and 95% of sickness and untimely deaths come from chronic hepatitis B and C virus infections. The epidemic of viral hepatitis B and C affects around 325 million people worldwide and is 10 times more than the global HIV epidemic. Hepatitis C virus (HCV), which is the main cause of hepatitis C, has a high mutation rate due to the lack of proofreading activity of the RNA polymerase enzyme. One of an attractive target for anti-HCV drug design and development is the NS3/4A serine protease. Whereas hepatitis B virus (HBV) infection can result in both acute and chronic diseases in the human liver. Current therapeutic drugs for HBV treatment are the nucleos(t)ide analogues (NAs) acting as competitive inhibitor against HBV reverse transcriptase (RT). In the present study, all-atom molecular dynamics (MD) simulations were performed to investigate the influence of the single point mutations (R155K and D168A) in the HCV genotype 1 NS3/4A protease on the structural dynamics, molecular interactions and susceptibility of asunaprevir (ASV). Principal component analysis (PCA) indicated that these two mutations caused a loss of the hydrogen bond network of residues R123--R155--D168. In addition, the free energy calculations based on different semiempirical QM/MM-GBSA methods revealed that the binding affinity of ASV with the two mutant forms was significantly decreased in the order of wild-type < R155K < D168A. In the case of HBV, MD simulations were performed on the HBV-RT in complex with anti-HIV drugs (stavudine, didanosine and zidovudine) and anti-HBV drug (lamivudine) to determine the ligand-protein interactions and binding efficiency towards the HBV-RT. The predicted binding free energies showed that stavudine had the binding affinity against HBV-RT similar to zidovudine and relatively better than the substrate and lamivudine. Afterward, the conformations of anti-HIV drugs in bound state with HBV-RT were investigated with their unbound form to elucidate the most stable conformation of anti-HIV drugs using replica exchange molecular dynamic. The results suggested that the conformations of all anti-HIV drugs in bound form were the most stable conformation. Moreover, the exploration of new potent drugs against HBV-RT, which were screened from the three-dimensional pharmacophore modeling was evaluated their anti-HBV activity. Based on pharmacophore-based screening and similarity search for 50% of nucleoside-based scaffold, the three commercial drugs, including floxuridine, trifluridine and sofosbuvir were selected. The *in vitro* study showed that floxuridine possibly reduced the HBV DNA but still had toxicity with hepatocytes. This research provided the useful structural information regarding the atomistic understanding of acquired drug resistance and a rational guidance for antiviral drug design and development.

ACKNOWLEDGEMENTS

I would like to thank my advisor, Assistant Professor Dr. Thanyada Rungrotmongkol for guidances, understanding and support during my study.

My gratitude is also extended to the chairman and thesis committees, Assistant Professor Dr. Kanoktip Packdibamrung, Assistant Professor Dr. Rath Pichyangkura, Professor Dr. Supot Hannongbua and Associate Professor Dr. Kiattawee Choowongkomon for their valuable suggestions.

I also thank all staff members and students of Department of Biochemistry, Faculty of Science, Chulalongkorn University for helpful assistance, friendship and making my time at the department enjoyable and memorable. My sincere thank is also extended to the Structural and Computational Biology Research Group and Computational Chemistry Unit Cell (CCUC) and the Center of Excellence in Hepatitis and Liver Cancer. Sincere thanks are expressed to all members of Biosim Lab, especially Mr. Kowit Hengphasatporn, Mr. Bodee Nutho and Mr. Panupong Mahalapbutr, for their help and suggestions.

This research is supported by the Scholarship from CU to develop research potential for the Department of Biochemistry, Faculty of Science, CU (Ratchadaphiseksomphot Endowment Fund) and the 90th Anniversary of CU Scholarship. Through travel grants for a short research visit, this research was also supported by the ASEAN-European Academic University Network (ASEA-UNINET) and the Institute for Molecular Science International Internship Program in Asia (IMS-IIPA).

Finally, I would like to thank my family for their support, encouragement and understanding.

Jirayu Kammarabutr

CHAPTER I

INTRODUCTION

Viral Hepatitis has become a public health challenge of global proportion which caused 1.34 million deaths in 2015, indicating a number comparable to deaths caused by tuberculosis and higher than those caused by HIV. However, the number of deaths due to viral hepatitis is increasing over time, while mortality caused by tuberculosis and HIV is declining. Most viral hepatitis deaths in 2015 were due to chronic liver disease with 720,000 deaths by cirrhosis and primary liver cancer with 470,000 deaths due to hepatocellular carcinoma. Although there are 5 distinct types of viral hepatitis (A-E), chronic hepatitis B and C cause 95% hepatitis related sickness and untimely deaths. Hepatitis D is less common and occurs only in association with hepatitis B. The other viruses (A & E) are spread via contaminated food, water and cause acute infections and outbreak in areas of poor sanitation and inadequate waste disposal [1]. Acute infections are often short-lived and resolve within a few weeks. The epidemic caused by hepatitis B virus (HBV) affects mostly the African Region and the Western Pacific Region. The epidemic caused by hepatitis C virus (HCV) affects all regions, with major differences between and within countries. The epidemic of both viral hepatitis B and C affects 325 million people globally and is 10 times larger than the global HIV epidemic. In Africa, chronic viral hepatitis affects over 70 million Africans (60 million with hepatitis B and 10 million with hepatitis C). Antiviral medicines can cure more than 95% of persons with hepatitis C infection, thereby reducing the risk of death from liver cancer and cirrhosis, but access to diagnosis and treatment is low. In addition, there is currently no vaccine for hepatitis C. For HBV, a vaccine has been available since 1982. The vaccine is 95% effective in preventing infection and the development of chronic disease and liver cancer due to hepatitis B. Viral hepatitis can now be treated with new simple oral medications which cure hepatitis C infections within 12 weeks and effectively control chronic Hepatitis B infection with longer term treatment. However, there were more new HBV and HCV infections than patients who were started on treatment. By the concept of target inhibition networks of antiretroviral (ARV)

regimen for a treatment-naive patient, two from three of drugs were nucleoside reverse transcriptase inhibitors (NRTIs) and protease inhibitor (PI) which targeted reverse transcriptase and protease of virus, respectively. These two enzyme also occurred in both HCV and HBV, suggesting that reverse transcriptase and protease are the major target for inhibiting viral hepatitis.

1.1 Hepatitis C virus

1.1.1 Genomic organization

HCV is a small (50-80 nm in size) enveloped RNA virus belonging to the *Hepacivirus* genus of the *Flaviviridae* family [2]. The HCV particle consists of a nucleocapsid, which contains the positive single-stranded RNA genome of approximately 9.6 kb, which contains an open reading frame (ORF) encoding a polyprotein precursor of approximately 3000 residues flanked by untranslated regions (UTRs) at both ends covered by a host cell-derived lipid envelope [3]. The precursor is cleaved into at least 10 different proteins: the structural proteins Core, E1, E2 and p7, as well as the non-structural proteins NS2, NS3, NS4A, NS4B, NS5A and NS5B (**Fig. 1**). The E1 and E2 regions are the most variable, while the 5'UTR and terminal segment of the 3'UTR have the highest degree of sequence conservation among various isolates. The 5'UTR, which is ~341 nucleotide in length, contains an internal ribosomal entry site (IRES), which is essential for cap-independent translation of viral RNA, from which four highly structured domains are produced. The 3'UTR varies between 200 and 235 nucleotide in length, including a short variable region, a poly(U/UC) tract with an average length of 80 nucleotide, and a virtually invariant 98 nucleotide X-tail region. The X region forms three stable stem-loop structures that are highly conserved among all genotypes. It appears that the 3'X region and the 52 nucleotide upstream of the poly(U/C) region, are crucial for RNA replication, while the remainder of the 3'UTR plays a role in enhancement of replication.

Figure 1 HCV genome organization and polyprotein processing

1.1.2 NS3/4A protease complex

NS3 is a multi-functional viral protein containing a serine protease domain in its N-terminal third and a helicase/NTPase domain in its C-terminal two-thirds. NS4A is a cofactor of NS3 protease activity. NS3/4A is a complex bifunctional molecule essential for viral polyprotein processing and RNA replication [2, 4]. The catalytic triad is formed by residues His 57, Asp 81 and Ser 139 of NS3. It catalyzes HCV polyprotein cleavage at the NS3/NS4A, NS4A/NS4B, NS4B/NS5A and NS5A/NS5B junctions. The central portion of NS4A is important for efficient processing of the nonstructural proteins by NS3. The central region of NS4A acts as a cofactor of NS3 serine protease activity, allowing its stabilization, localization at the ER membrane as well as cleavage-dependent activation, particularly at the NS4B/NS5A junction.

1.1.3 Global prevalence and genotype distribution of hepatitis C virus infection

Currently, HCV infects over 185 million people and long-term HCV-infected patients are under an increased risk of developing liver diseases, such as cirrhosis and hepatocellular carcinoma. HCV strains are classified into seven recognized genotypes (1-7) on the basis of phylogenetic and sequence analyses of whole viral genomes. Genotype 1 is the most common HCV genotype worldwide, accounting for 83.4 million (46.2%) with over one-third of genotype 1 cases located in East Asia. HCV genotype 3 is the next most common and is estimated to account for 54.3 million (30.1%) cases globally, approximately three-quarters of which occur in south Asia. Genotypes 2, 4, and 6 are responsible for the majority of the remaining cases of HCV worldwide, with an estimated 16.5 million (9.1%), 15.0 million (8.3%), and 9.8 million (5.4%) cases, respectively. East Asia accounts for the greatest numbers of genotype 2 and genotype 6 HCV cases, while North Africa and the Middle East have the largest number of genotype 4 cases. It has been reported that genotype 1 is the most common genotype in 85 of the 117 countries and is highly prevalent worldwide [5]. Genotype 2 dominated in West Africa, genotype 3 in south Asia and parts of Scandinavia, genotype 4 in Central and North Africa, Genotype 5 in South Africa, and genotype 6 in SE Asia [5]. The diversity of genotypes is high in China and many Southeast Asian countries

1.1.4 HCV life cycle

1.1.4.1 Attachment and entry

Attachment of the virus to a cell followed by viral entry is the first step in the virus life cycle. In order to enter the host cell, the virus must first bind to a receptor on the cell surface. After attachment, the nucleocapsid of enveloped viruses is released into the cell cytoplasm as a result of a fusion process between viral and cellular membranes. The entry process is controlled by viral surface glycoproteins that

trigger the changes required for mediating fusion. By analogy, HCV envelope glycoproteins are believed to belong to class II fusion proteins. However, HCV envelope glycoproteins do not appear to require cellular protease cleavage during their transport through the secretory pathway. HCV entry into cells is pH-dependent and endocytosis-dependent but the identity of the HCV fusion peptide remains unclear.

1.1.4.2 Translation and post-translational processing

Decapsidation of viral nucleocapsids releases free positive-strand genomic RNAs into the cell cytoplasm, where they serve, together with newly synthesized RNAs, as messenger RNAs for synthesis of the HCV polyprotein. HCV genome translation is under the control of the IRES of the 5'UTR and the first nucleotides of the core-coding region. The HCV IRES has the capacity to form a stable pre-initiation complex by directly binding the 40S ribosomal subunit without the need of canonical translation initiation factors. This binary complex then binds to eukaryotic initiation factor 3 [6], as well as the ternary complex eIF-2, GTP, to form a 48S-like complex. A second GTP hydrolysis step involving initiation factor eIF5B then enables the 60S ribosomal subunit to associate, forming a functional 80S ribosome that initiates viral protein synthesis.

1.1.4.3 Polyprotein processing

The main translation product of the HCV genome is a large precursor polyprotein that is subsequently processed by cellular and viral proteases into mature structural and nonstructural proteins (**Fig. 1**). From the hydrophobicity profile and dependence on microsomal membranes, junctions at core/E1, E1/ E2, E2/p7, p7/NS2 are processed by host signal peptidases. Cleavage by the host signal peptidase yields the immature form of the core protein. The signal peptide is further processed by a host signal peptide peptidase (SPP) to yield the mature form of the core protein. HCV nonstructural proteins are processed by two viral proteases: cleavage between NS2

and NS3 is a rapid intramolecular reaction mediated by a NS2-3 protease spanning NS2 and the N-terminal domain of NS3. In contrast, the remaining four junctions are processed by the NS3 protein. The NS3-NS5B region is presumably processed by sequential cleavage: NS3/4A>NS5A/5B>NS4A/4B>NS4B/5A.

1.1.4.4 RNA replication

HCV replication is assumed to start with synthesis of a complementary negative-strand RNA using the positive-strand genome RNA serves as a template. In The second step, negative-strand RNA serves as a template to produce numerous strands of positive polarity that will subsequently be used for polyprotein translation, synthesis of new intermediates of replication or packaging into new virus particles, both steps of which are catalyzed by the NS5B RdRp. The positive-strand RNA progeny is transcribed in a five to ten fold in excess compared to negative-strand RNA. NS5B RpRd was initially thought to catalyze primer-dependent initiation of RNA synthesis, either through elongation of a primer hybridized to the RNA template or through a copyback mechanism.

1.1.4.5 Viral assembly and release

As with related viruses, the mature HCV virion likely consists of a nucleocapsid and outer envelope composed of a lipid membrane and envelope proteins. The N-terminal half of the core protein is important for nucleocapsid assembly. Nucleocapsid assembly generally involves oligomerization of the capsid protein and encapsidation of genomic. This process is thought to occur upon interaction of the core protein with viral RNA, and the core-RNA interaction may be critical for switching from RNA replication to packaging. Once a HCV nucleocapsid is formed in the cytoplasm, it acquires an envelope as it buds through an intracellular membrane. Interactions

between the core and E1/E2 proteins are thought to determine viral morphology. HCV particles are released from the cell through the secretory pathway [2, 4].

1.1.5 Treatment of HCV infection

The currently used anti-HCV agents are targeted inhibitors against the important NS3/NS4A protease, NS5B polymerase and NS5A viral proteins [7]. For the treatment of HCV patients, the combination of PEGylated-interferon- α and ribavirin is extremely expensive but only effective for ~50% of HCV patients [8, 9]. Moreover, this therapy causes several adverse side effects, including alopecia, rash/itching, nausea, thrombocytopenia and anaemia. Consequentially the NS3/4A protease has become one of the attractive targets for anti-HCV drug design and development [4]. Importantly, the NS3 proteolytic activity and the acceleration of the cleavage rate are associated with the NS4A cofactor [10]. The HCV therapy has been improved by the use of boceprevir [11-13] and telaprevir [14, 15], which specifically inhibit the NS3/4A protease enzyme. Although this treatment leads to an increased rate of sustained virologic response, such therapeutic drugs have a low success rate [16]. Recent drugs, such as simeprevir [17, 18] and vaniprevir [19, 20], were approved for the treatment of HCV-infected patients in 2013 and 2014, respectively. In addition, other inhibitors are currently used in clinical studies such as danoprevir [21, 22], grazoprevir [23], faldaprevir [24], vedroprevir [8] and asunaprevir (ASV; [25, 26]). Because HCV lacks a proofreading activity of its RNA polymerase enzyme, high mutation rates in response to the treatments have been widely reported, resulting in resistance to drugs/inhibitors [27-30]. ASV is a second-generation NS3/4A protease inhibitor that was approved for use in combination with daclatasvir in Japan for the treatment of HCV genotype 1-infected patients [31]. However, ASV has not yet been approved in the USA and Europe, where it is currently in phase III clinical trials [32]. This compound shows a strong antiviral activity against genotypes 1 and 4 of HCV [25, 26]. From *in vitro* studies, the

acquired resistance against ASV caused by the two single point mutations of R155K and D168A in the NS3/4A protease results in a lower susceptibility to ASV, with an ~21- and 23-fold reduced half maximal effective concentration (EC_{50}), respectively [29]. These two mutated residues are located near the protease active site (**Fig. 2**) and were also found to reduce the binding affinities of some other anti-HCV inhibitors, such as danoprevir [21, 22], simeprevir [17, 18] and grazoprevir [23], by changing the conformation of the active site [33-35]. For instance, the absence of a Nε, which is the nitrogen atom at epsilon position, of residue K155 prevented the interaction between residues 155 and 168, which disrupted the interaction of ASV with the target protein [36].

Figure 2 **(A)** Chemical structure of ASV, in which the P1', P1, P2, P3 and P4 substituents are shaded by black, pink, purple, blue and orange, respectively. **(B)** Three-dimensional structure of the ASV-NS3/4A complex, where the acquired resistance caused by the R155K and D168A point mutations towards the NS3/4A protease is also shown.

1.2 Hepatitis B virus

1.2.1 Genomic organization

HBV is a small enveloped DNA virus that classify to the family Hepadnaviridae, genus Orthohepadnavirus. Hepadnaviruses are para-retroviruses which reverse transcription occurs in the virus-producing cell from pregenomic RNA (pgRNA) [37]. HBV contains an open circular DNA genome, which is partially double-stranded and contains overlapping protein reading frames over much of its length, corresponding to a high information density (**Fig. 3**). The partially double-stranded DNA is represented in both the minus- and plus-strands, with the variably extended region of the plus-strand shown dashed, the direct repeats marked and the RNA primer shown as a zig-zag. The ribosome binding sites are shown as grey arrows. The overlap over most of the genome and are labelled C (and preC) for the core (and pre-core), P for the polymerase, E for the envelope proteins (with the large, medium and small surface proteins shown outside as dotted lines, to show the preS1 and preS2 at the N-termini) and X for protein X [37, 38].

1.2.2 HBV life cycle

HBV infects only hepatocytes and binds specifically to an unknown receptor on the pre-S1 region of the surface protein which is attached on the liver cell membrane. Presently, the precise mechanism of viral entry has not been reported yet. However, the mechanism of viral entry that the viral particle passes through cellular plasma membrane of liver cell by fusion of the viral membrane and cellular plasma membrane have been proposed as potential pathway [38]. The virus binds to the sodium taurocholate co-transporting polypeptide (NTCP) receptor on the surface of hepatocytes and is endocytosed, releasing its DNA-containing nucleocapsid into the cytoplasm. After core is released into the cytoplasm and transport relaxed circular DNA (rcDNA) containing nucleocapsid to the host nucleus, the rcDNA is repaired at the nick

in the minus-strand and the gap in the plus-strand by both viral and cellular enzymes to form covalently closed circular DNA (cccDNA) as shown in **Fig. 4**. This process aims to produce the cccDNA in the nucleus [39].

Figure 3 Genomic map for hepatitis B virus [37]

Integration of HBV DNA into the host genome also takes place. The cccDNA functions as a mini-chromosome and template for transcription of viral RNA. Due to the long half-life of hepatocytes, cccDNA will persist indefinitely within the host hepatocyte nucleus, thereby serving as a reservoir for reactivation of viral replication. The cccDNA consists of the precore/core gene, the polymerase gene, the PreS1/L-, PreS2/M- and Surface/S-gene and the X gene. The precore/core gene is coded for the nucleocapsid protein and for the secreted, non-structural, precore protein, the HBV

envelope antigen (HBeAg). Other three genes, the PreS1/L-, PreS2/M- and Surface/S-gene, are coded for the three envelope proteins.

Figure 4 The hepatitis B virus and replication cycle [39]

CHULALONGKORN UNIVERSITY

The enveloped virions bind to the host cell by an unknown PreS1 region. The protein X has been suggested to be involved in many control processes in the infected cell, resulting in increased synthesis of viral proteins and also possible inhibition of apoptosis of the infected cell. Unfortunately, the mechanism of X protein is still the least understood. The cccDNA is transcribed into subgenomic RNA (sgRNA) and pregenomic RNA (pgRNA). The self-assembly of the RNA-containing viral nucleocapsid occurred via complex formation of the pgRNA with core protein and polymerase (RT domain). The assembly starts when the RT binds to a short hairpin element located

on the pgRNA. The RT in complex with RNA acts as the nucleus for assembly of core protein. This enzyme also consists of a terminal protein (TP) domain containing a tyrosine residue which acts as the primer for addition of the first deoxynucleotide triphosphate during synthesis of the minus-strand of the viral DNA. As the RT bound to pgRNA at a specific site (ϵ region) near 5'-terminus in Core assembly process, DNA synthesis starts copying specific sequence in ϵ region by receiving first deoxynucleotide triphosphate onto a tyrosine residue in the active site of the RT [37, 38]. The synthesis of minus-strand DNA proceeds through the 5'-direct repeat (DR1) to the 5'-terminus of pgRNA where it keeps for any further template. At this process, the primer DNA shifts from the 5'-DR1 onto the 3'-DR1, allowing further elongation of the primer. The RNase H activity starts to degrade the pgRNA (template) as the minus-strand DNA grows which means that an RNA/DNA double helix is the substrate for RNase H. After the RT reaches the 5'-terminus of the pgRNA for the second time, it will have a second minus-strand DNA with terminal repeats in the same orientation and a short RNA fragment, degrading by RNase H from the template. The short RNA fragment will hybridize to the 3'-DR1 region of the minus-strand DNA which it acts as the initial primer for the plus-strand synthesis. The synthesis of the DNA plus-strand begins when the end of the single strand DNA are close together which allow the primer (RNA fragment) to move from 3'-DR1 onto DR2 of minus-strand. After the 3'-end of primer bind to the 3'-DR1 of the minus-strand, the plus-strand is now ready for elongation process catalyzed by the RT function. These RNA-containing cores are still immature which are not ready to envelop and do not normally interact with the surface protein, until double-stranded DNA has been formed. The nucleocapsids are not only re-imported to the nucleus but also enveloped and released via the endoplasmic reticulum (ER). In case of import to the nucleus, the pgRNA is reverse transcribed into negative-strand DNA by the RT inside the nucleocapsid (as describe above). Afterwards, rcDNA is created by plus-strand synthesis from the negative-strand DNA for cccDNA amplification in the nucleus. On

the other hand, in cytoplasm, RNA-containing nucleocapsids undergo a maturation process to DNA containing nucleocapsids by reverse transcription from pgRNA to pgDNA. After import into the ER lumen, the envelope proteins are secreted by the cell either as small, non-infectious subviral spherical (SVRs) or as infectious virions. Especially, the non-infectious SVPs are produced in a thousand to million fold excess over virions [37, 38].

1.2.3 Reverse transcriptase (RT)

The RT is an enzyme used to synthesize the complementary poly-DNA by utilizing both poly-RNA and poly-DNA as template, a process termed reverse transcription [40]. These enzymatic activities have been referred to as RNA-dependent DNA polymerase and DNA-dependent DNA polymerase activity. The two activities are appeared to share a common active site and have very similar heat inactivation profiles [40, 41]. As like known DNA polymerase, the RT also requires a primer to initiate DNA synthesis which both ribo and deoxyribo-oligomers can used as primer. The efficiency of transcription differs with the source of reverse transcriptase and the divalent cations used in the reaction. However, the RT lacks proofreading activity due to the absence of 3'-5' exonuclease activity [42]. For instance, RT from avian myeloblastosis virus [43] shows the large number of incorrectly paired bases when copying ribopolynucleotide and deoxyribopolynucleotide templates. Importantly, the frequency of error of RT from AMV is 1 in 600 when transcribing homopolymer templates and 1 in 6000 when copying alternating copolymer templates. Moreover, the RT can specifically degrade the RNA moiety of an RNA-DNA hybrid by RNase H activity. The degradation is independent on the synthesis of complementary DNA since preformed hybrids are susceptible to degradation [44, 45]. This enzyme acts as an exoribonuclease differ from cellular RNase H which is an endoribonuclease [46, 47]. A processive nuclease is defined as an enzyme which once bound to the polynucleotide chain substrate

completely degrades the substrate before being released. In addition, the digested RNA product has a phosphate-5' and 3'-OH, suggesting that the degraded RNA template can act as primer for the synthesis of the second strand of DNA. From all available data indicate that DNA polymerase and RNase H activities reside on the same polypeptide which has different functional sites [40, 41, 47, 48].

1.2.4 Diagnosis

To diagnose the HBV infection, commercially available serological tests are used to detect HBV surface antigen (HBsAg), HBeAg, HBV surface antibody (anti-HBs), HBV core antibody (anti-HBc), HBV envelope antibody (anti-HBe), and HBV DNA [39]. Note that Chronic HBV infection is defined as detection of HBsAg on 2 times measured at least 6 months apart. Diagnosis of acute and chronic HBV infection can classify into 4 cases: HBV infection, resolved infection, immunity and isolated core. Individuals who present HBsAg for more than 6 months are defined chronic infection. Individuals with chronic HBV infection are typically asymptomatic and are diagnosed during routine health maintenance or screening. In case of acute infection, anti-HBc will be detected in the form of immunoglobulin M (IgM). Only 5 to 10% of individuals with acute HBV infection will progress to chronic HBV infection. Interestingly, only one-third of individuals develop symptoms such as fever, fatigue, malaise, abdominal pain and jaundice during an acute HBV infection. Among individuals who recover from HBV infection, 80% will develop anti-HBs and all will develop anti-HBc which is presented in form of immunoglobulin G (IgG) [39]. Besides, HBsAg is now no longer detected in this case. Thus, testing for anti-HBc is important for identifying individuals who may have been previously infected. Essentially, individuals younger than 19 years should be vaccinated, resulting in gaining immunity. Only anti-HBs will be detected in immunity case. Note that individuals with anti-HBs levels less than 10 IU/L are considered not immune.

1.2.5 Phases of HBV Infection

Individuals with chronic HBV infection can transition between periods of immunologic activity and inactivity several times during a lifetime. Chronic HBV infection is divided into 4 phases: HBeAg-positive immunotolerance disease, HBeAg-positive immunoreactive disease, HBeAg-negative inactive disease (inactive chronic HBV or low replicative), and HBeAg-negative immunoreactive disease. There are 2 immunologically active phases, including the HBeAg-positive immunoreactive phase and HBeAg-negative immunoreactive phase, and 2 immunologically inactive phases, including the HBeAg-positive immunotolerance phase and the HBeAg-negative inactive phase. Individuals in the immunotolerance and HBeAg-negative inactive disease phases are asymptomatic while individuals in the HBeAg-positive immunoreactive and HBeAg-negative immunoreactive disease phases can transition from asymptomatic to liver failure. To determine the phase of chronic HBV infection, the serological markers are used to detect the presence or absence of HBeAg and anti-HBe, the quantity of HBV DNA (HBV DNA level), level of alanine aminotransferase (ALT; known as a sensitive marker of liver inflammation) and the presence or absence of intrahepatic necroinflammation and fibrosis. The use of these biomarkers shows the presence of intrahepatic immunologic activity which provides a damage level of liver cell. More importantly, combining these biomarkers is important in determining the need for treatment initiation [39]. Individuals with acute HBV infection are positive for HBeAg. With the progress from acute HBV infection to chronic HBV infection, individuals can become negative for HBeAg (loss of HBeAg). The transition from positive to negative of HBeAg is associated with a decrease in HBV DNA level (<2,000 IU/mL) and suspension of liver inflammation and injury which is in the HBeAg-negative inactive disease phase. However, the duration of each phase is not well known, but most individuals with chronic HBV infection who infected perinatally have undergone HBeAg loss and only 6 to 10% of adults older than 40 years remain positive for HBeAg. During the course of

chronic HBV infection, the loss of HBsAg with or without seroconversion to anti-HBs and an undetectable HBV DNA level in the peripheral blood may occur which is associated with improved survival and reduced risk of liver failure and hepatocellular carcinoma.

1.2.6 Global prevalence and genotype distribution of hepatitis B virus infection

Hepatitis B virus (HBV) is a major health public problem, infecting over 240-257 million people worldwide. Chronic hepatitis B infection is defined as the detection of serum hepatitis B surface antigen (HBsAg; the viral glycoprotein) after 6 months of infection. By the infected with chronic hepatitis B virus, it can progress to low-grade liver inflammation, with episodes of transient high-grade liver inflammation and activation of fibrogenic processes, leading to liver fibrosis and cirrhosis, which may culminate in decompensated (symptomatic) liver disease and/or the development of hepatocellular carcinoma (HCC) in 25–40% of HBV carriers [39, 49]. In addition, HBV infection has further oncogenic potential after HBV integration into the host genome, which is an additional pathway contributing to HCC. Hepatocellular carcinoma and cirrhosis represent the fifth and the ninth most common cancer in males and females, causing 88,700 deaths in 2015 [50]. The prevalence of HBV infection in the general population depends on the region and ranges from 0.01% in northern European countries to 22.3% in the Pacific region (3–5). In Europe, the average HBV prevalence has been estimated at 1.5%, with 15 million people infected [1, 51].

There is 10 different HBV genotypes (A-J), according to the difference in overall genomic sequences or in sequences of gene coding surface antigen, with a distinct geographic distribution have been discovered which show the highest prevalence of HBV in Central and east Asia, sub-Saharan Africa and the Pacific regions [39]. Genotype A is most common found in northern Europe, North America, India, and Africa, while

genotype B and C are most prevalent in southeast Asia [51]. Genotype D is most prevalent in southern Europe, the Middle East, and India [43, 52]. In Europe, genotypes A and D were found to be most prevalent [53]. Genotype A is further divided in subtypes A1–A4. Subtypes A1, A3, and A4 are mainly found in Africa, whereas A2 prevails in northern and central Europe and in North America [52]. In addition, there are nine known subtypes of HBV genotype D [54]. HBV subtype D1 is predominant in the Middle East and North Africa, subtype D2 has been found in Albania, Turkey, Brazil, western India, Lebanon, and Serbia, and subtype D3 in Serbia, western India, and Indonesia. Subtype D4 has been rare and has been reported from Haiti, Russia, the Baltic countries, Brazil, Kenya, Morocco, and Rwanda. Subtype D5 is common in eastern India, subtype D6 in Indonesia, Kenya, Russia, and the Baltic region, and subtype D7 in Morocco and Tunisia. Subtypes D8 and D9 have recently been discovered and reported from West Africa and India [54]. For other genotypes, there were present in Europe sporadically, with most cases being imported to Europe either as a consequence of immigration from the Middle East, Asia, and Africa in past decades, or imported by European travelers that were infected abroad. Currently, HBV infected people still suffer from chronic hepatitis B even though the HBV vaccine shows 95% effective because most of the current HBV infected patients were born before the vaccine was widely accessible [50].

1.2.7 Treatment of HBV infection

There are 7 antiviral treatments for chronic HBV infection available in the United States which can be classify into 2 groups: interferons and nucleos(t)ides analogues. Interferons (alfa, beta, and gamma) are cytokines that are endogenously produced by immune system cells in response to viral infections and was approved in 1991 [39, 50]. Afterwards, it will be substituted by its pegylated form (Peg-IFN). The mechanism of Peg-IFN therapy related on the induction of long-term immune control

in response to viral infections (host immunomodulation effects) including boosting host immune response against infected hepatocytes, facilitating viral clearance. Nevertheless, the exact mechanism of an antiviral effect is not clear yet, but it is also believed to have direct antiviral including degradation of cccDNA and viral mRNA and inhibition of viral DNA. Even though all type of interferons have antiviral and immunomodulatory effects, but only alfa and beta interferons show more potent antiviral actions. Regardless, this antiviral treatment still has significant drawbacks such as an adverse safety profile and high response variableness which is ineligible and unsuitable for many patients. The adverse effects include flu-like symptoms: asthenia, pyrexia, myalgia and headache; thyroid dysfunction; gastrointestinal symptoms: nausea, diarrhea and decreased appetite; psychiatric disorders: depression and insomnia; dermatologic disorders: alopecia and pruritus; neutropenia; thrombocytopenia [55]. The best treatment response of Peg-IFN occurs in patients with HBV genotype A infection. In randomized clinical trials, Peg-IFN achieved higher rates of HBeAg loss, compared with lamivudine. Long-term treatment with interferon has demonstrated an association between therapeutic response (with HBeAg loss and sustained HBV DNA suppression) and higher incidence of HBsAg loss, improved liver histology and a reduction in cirrhosis and hepatocellular carcinoma compared with untreated controls. However, overall responses remain suboptimal in that only approximately one-third of patients achieve HBeAg loss and fewer achieve HBsAg loss [50].

NAs are widely used as anti-HBV drug agents against HBV and also HIV infections. The current NAs for HBV treatment include lamivudine (3TC) [56], telbivudine (TBV) [6], adefovir dipivoxil (ADV) [57], tenofovir disoproxil fumarate (TDF) [58], tenofovir alafenamide [59] and entecavir (ETV) [60]. The NAs are phosphorylated by intracellular kinases to form their diphosphate or triphosphate active forms. The active form of NAs prevents additional dNTPs from being incorporated by replacing themselves into HBV-

RT active site instead of dNTPs in elongating DNA strand [50, 61]. As the HBV-RT is homologous to the human immunodeficiency virus type 1 reverse transcriptase (HIV-1 RT), it could be reasonable to use HIV-1 RT drugs against HBV-RT [62]. The approved HIV drugs have been discovered, including stavudine (d4T) [63], didanosine [64], and zidovudine (ZDV) [65]. 3TC is the first oral NA approved by the United States Food and Drug Administration (FDA) for the treatment of chronic hepatitis B infection in 1998 [66] and has been the most experienced oral antiviral in chronic hepatitis B infection patients [67, 68]. However, long-term treatment of 3TC is associated with high rates of drug resistance, which lead to virological relapse and biochemical flare [66, 68, 69]. Therefore, 3TC is recommended as a second-line therapy for the treatment of chronic hepatitis B infection [66, 69]. d4T, known as synthetic analogue of thymidine, is a highly potent inhibitor of HIV-1 replication in vitro. About 40 % of d4T is renally eliminated by glomerular filtration and tubular secretion [63, 70]. Peripheral neuropathy, observed in about 12 % of patients, is the most important adverse effect of d4T [70, 71]. DDI is an analogue of deoxyadenosine and renally eliminated like d4T [64, 70]. The most significant toxicities associated with the use of DDI are pancreatitis, peripheral neuropathy, hepatic steatosis, and lactic acidosis, which are manifestations of mitochondrial toxicity. Peripheral neuropathy, observed in approximately 20 % of individuals, while pancreatitis may occur in 1 to 7 % of patients, resulting in rarely used because of toxicity [70, 72]. Next, ZDV is a pyrimidine analogue, has an azido group substituting for the 3'hydroxyl group on the ribose ring [65, 70]. Clinical use of this drug has evolved from use as monotherapy to use in combination with other antiretroviral drugs (ARVs). With long-term use, the predominant adverse effect of ZDV is myelosuppression, including neutropenia and anemia, which have been shown to occur in 16 and 24 % of patients, respectively [70, 73]. This drug also is associated with myopathy, lactic acidosis, and hepatic steatosis, resulting from mitochondrial toxicity. Importantly, ZDV overdose has been observed in neonates, receiving postnatal HIV

prophylaxis, which there was a self-limited lactic acidosis and neutropenia in most cases [74, 75]. From *in vitro* studies, these compounds demonstrated well tolerate, excellent oral bioavailability, significant susceptibility to HIV [63, 65, 76] and has also been reported to inhibit HBV-RT activity. For instance, ZDV shows inhibition activity against HBV-RT by 21 to 41 percentage of inhibition of activity by two repeated experiments [65, 77].

Figure 5 **A)** The 3D structure of HBV-RT composing of three subdomains: finger (blue), palm (red) and thumb (green) in complex with double-stranded DNA (grey), two Mg^{2+} (dark green) and dTTP substrate. **B)** The 2D chemical structures of anti-HBV and anti-HIV drugs. **C)** The topological angle (θ), torsional angle (τ),

distance (r) and the name of linked atoms were labeled and illustrated in nucleotides containing pyrimidine base.

1.3 Objectives

- i) To investigate the effect of such mutations on the ASV binding to NS3/4A, in terms of the inhibitor-protein interactions and binding efficiency towards the HCV NS3/4A protease
- ii) To understand structural properties and interaction of HIV drugs including stavudine, didanosine and zidovudine against HBV-RT
- iii) To study the various possible conformations change of anti-HIV drugs in unbound form and bound form with HBV-RT
- iv) To screen for drugs that are potentially effective as anti-HBV and anti-HIV drugs against HBV-RT
- v) To investigate the inhibitory activity of anti-HIV drug and other drugs from screening against HBV

CHAPTER II

THEORIES

2.1 Homology modeling

Homology modeling is the computational approaches for protein three-dimensional structure modeling and prediction. Homology modeling builds an atomic model based on experimentally determined known structures that have sequence homology of more than 40%. It is also known as comparative modeling. If two proteins share a high sequence similarity, they are likely to have very similar three-dimensional structures. If one of the protein sequences has a known structure, then the structure can be copied to the unknown protein with a high degree of confidence. Homology modeling is moderately accurate for the positions of alpha carbons and inaccurate for side chain positions and loops. The others approaches are threading for <40% similarity and *ab initio* prediction for no homolog. Homology modeling divides into 3 types: basic modeling, advanced modeling and iterative modeling [78].

2.1.1 The overall homology modeling procedure

2.1.1.1 Template selection

The template selection involves searching the Protein Data Bank (PDB) for homologous proteins with determined structures. The search can be performed using a heuristic pairwise alignment search program like BLAST or FASTA. A database protein should have at least 40% sequence identity, highest resolution and the most appropriate cofactors for it to be a template sequence.

2.1.1.2 Sequence alignment

Once the template is identified, the full-length sequences of the template and target proteins need to be realigned using refined alignment algorithms to obtain optimal alignment.

2.1.1.3 Backbone model building

Once optimal alignment is achieved, the corresponding coordinates residues of the template proteins selected can be simply copied onto the target protein. If the two aligned residues are identical, coordinates of the side chain atoms are copied along with the main chain atoms. The average coordinate values of the templates are used in case of multiple templates.

2.1.1.4 Loop modeling

After the sequence alignment, there are often regions caused by insertions and deletions leads to gaps in sequence alignment. The gaps are modeled by loop modeling. The loops are generated by random many loops and searches for the one that has reasonably low energy and ϕ and ψ angles in the allowable regions in the Ramachandran plot.

2.1.1.5 Side chain refinement

The positions of side chains will be determined after the main chain atoms are built. A side chain can be built by searching every possible conformation by every torsion angle of the side chain to select the one that has the lowest interaction energy with neighboring atoms.

2.1.1.6 Model refinement and model evaluation

This step includes the energy minimization procedure on the entire model, which moves the atoms in such a way that the overall conformation has the lowest energy potential. The goal of energy minimization is to relieve steric collisions without altering the overall structure. In these loop modeling and side chain modeling steps, potential energy calculations are applied to improve the model. The final model has to be evaluated for checking the ϕ - ψ angles, chirality, bond lengths, close contacts and also the stereochemical properties.

2.2 Molecular dynamics (MD) simulation

The study of the molecular structure is a key point in the understanding of biology. Biological function is based on molecular interactions, and these are a consequence of macromolecular structures. To observe molecular interactions by experimental processes is difficult, expensive, and takes a long time. MD simulation is used to overcome the limitations. MD simulation has advanced from simulating several hundreds of atoms to systems with biological relevance, including entire proteins in solution with explicit solvent representations, membrane embedded proteins, or large macromolecular complexes like nucleosomes or ribosomes. These simulations can capture a wide variety of important biomolecular processes, including conformational change, ligand binding, and protein folding, revealing the positions of all of the atoms at femtosecond temporal resolution. Importantly, the simulations can also predict the biological response from perturbations such as mutation, phosphorylation, protonation, or the addition or removal of a ligand at an atomic level. Moreover, MD simulations are often used in combination with a wide variety of experimental structural biology techniques, including X-ray crystallography, cryoelectron microscopy (cryo-EM), nuclear magnetic resonance (NMR) and electron paramagnetic resonance [79]. The choice of a proper potential is the most importance in obtaining accurate MD

simulations [80-82]. An approximate potential may be calculated from quantum mechanics and from the Born-Oppenheimer approximation in which only the positions of the atomic nucleus bonding are considered. The potentials may be divided into bonding potentials and long-range potentials. The bonding potentials involve interaction with two atoms (bond stretching), three atoms (bond bending), and four atoms (dihedral). Long-range interactions are associated with the Lennard-Jones potential (van der Waal) and the Columbic potential [83, 84]. The MD simulation method is based on Newton's second law or the equation of motion, $F_i = m_i a_i$, where F is the force exerted on the i particle, m_i is mass and a_i is acceleration of the i particle. From knowledge of the force on each atom, the acceleration can be calculated by the first-order differential of velocity respect to time or second-order differential of the position respect to time. Nowadays, MD simulation is achieved on popular programs such as AMBER, CHARMM, ACEMD, GROMACS, or NAMD.

2.3 The molecular mechanics/Poisson-Boltzmann or generalized Born surface area (MM/PBSA and MM/GBSA) methods

Computational methods that combine molecular mechanics energy and implicit solvation models, such as Molecular Mechanics/Poisson Boltzmann Surface Area (MM/PBSA) and Molecular Mechanics/Generalized Born Surface Area (MM/GBSA), have been widely exploited in free energy calculations [85]. Both of MM/PBSA and MM/GBSA allow for rigorous free energy decomposition into contributions originating from different groups of atoms or types of interaction [86, 87]. In MM/PBSA or MM/GBSA, binding free energy (ΔG_{bind}) between a ligand (L) and a receptor (R) to form a complex (RL) is calculated as:

$$\Delta G_{bind} = \Delta H - T\Delta S \approx \Delta E_{MM} + \Delta G_{sol} - T\Delta S \quad (1)$$

$$\Delta E_{MM} = \Delta E_{internal} + \Delta E_{electrostatic} + \Delta E_{vdW} \quad (2)$$

$$\Delta E_{internal} = \Delta E_{bond} + \Delta E_{angle} + \Delta E_{dihedral} \quad (3)$$

$$\Delta G_{sol} = \Delta G_{PB/GB} + \Delta G_{SASA} \quad (4)$$

$$\Delta G_{SASA} = \gamma \cdot SASA + \beta \quad (5)$$

where ΔE_{MM} , ΔG_{sol} and $-T\Delta S$ are the changes of the gas phase MM energy, the solvation free energy and the conformational entropy upon binding, respectively. ΔE_{MM} includes $\Delta E_{internal}$ (bond, angle and dihedral energies), electrostatic for $\Delta E_{electrostatic}$ and van der Waals energies for ΔE_{vdW} . ΔG_{sol} is the sum of electrostatic solvation energy (polar contribution), $\Delta G_{PB/GB}$, and non-electrostatic solvation component (non-polar contribution), ΔG_{SASA} . The polar contribution is calculated using either GB or PB model, while the non-polar energy is estimated by solvent accessible surface area (SASA). The γ and β with the values of 0.00542 kcal/mol·Å² and 0.92 kcal/mol, respectively. The conformational entropy change $-T\Delta S$ is usually computed by normal-mode analysis on a set of conformational snapshots taken from MD simulations. MM/GBSA or MM/PBSA has been successfully applied to various protein-ligand or protein-protein/peptide complexes [88, 89]. In addition, MM/PBSA or MM/GBSA is sensitive to simulation protocols, such as sampling strategy of generating snapshots and entropy calculation methods as well as other parameters such as charge models, force fields, solute dielectric constant and radius parameters in continuum solvent models [90].

2.4 The quantum mechanics/molecular mechanics generalized Born surface (QM/MM-GBSA) method

The quantum mechanics/molecular mechanics (QM/MM) approach is a molecular simulation method that combines the strengths of the QM (accuracy) and MM (speed) approaches, achieving the prediction of ligand binding affinity and substrate specificity. The QM/MM-GBSA approach was calculated in the same manner as the MM/GBSA but the H term was computed by a hybrid of quantum mechanics (QM) and molecular mechanics (MM) [91, 92]:

$$E_{total} = E_{QM} + E_{MM} + E_{QM/MM} \quad (6)$$

where E_{QM} is energy of the QM region, E_{MM} is the energy of the MM region and $E_{QM/MM}$ is the interaction between QM and MM region.

2.5 The Replica-exchange molecular dynamics (REMD) method

It is usually difficult to obtain accurate canonical distributions at low temperatures by conventional simulation methods because simulations at low temperatures tend to get trapped in one of a huge number of local minimum-energy states. One way to overcome this multiple-minima problem is to perform a simulation based on non-Boltzmann probability weight factors so that a random walk in energy space may be realized. Random walks allow the simulation to pass any energy barrier and to sample a much wider phase space than by conventional methods. One recently approach to increase conformational sampling is parallel tempering. The parallel tempering, or the replica exchange MD (REMD) method, has emerged as one of the most widely used methods to enhance conformational sampling [93-95]. Several replicas of the system are simulated independently in parallel, under different conditions. At predefined intervals, neighboring pairs of replicas are exchanged with a specific transition probability. In most REMD studies, the temperature is used as the parameter that changes among the replicas. Exchanging temperatures allows conformations that are trapped in local minima at a low temperature to escape by passing to a higher temperature condition. Temperature based REM (T-REM) combines simulated tempering and multicopy simulations in a thermodynamic correct manner. Using T-REM, N independent copies (replicas) of the systems are propagated simultaneously at different fixed temperatures. At regular intervals pairs of replicas at successive temperatures are exchanged according to a Metropolis criterion allowing individual replicas to sample a range of temperatures. The exchange probability between two replicas (i and j) is calculated as:

$$P(i,j) = \exp(-\Delta) \quad (9)$$

$$\Delta \equiv [\beta_i - \beta_j] (E_i - E_j) \quad (10)$$

$$\beta = 1/k_B T \quad (11)$$

where E is the potential energy of the system, T is the absolute temperature, and k_B is Boltzmann's constant. At higher temperatures the increased thermal energy facilitates the exploration of conformational space and allows the system to cross barriers not readily crossed at the temperature of interest on a given time scale.

2.6 The pharmacophore-based virtual screening

The concept of pharmacophores is based on the assumption that the molecular recognition of a biological target shared by a family of compounds can be described by a set of common features that interact with a set of complementary sites on the biological target. The features are quite general such as hydrogen-bond donors, hydrogen-bond acceptors, positively and negatively charged or polarizable, hydrophobic regions, or metal-ion interactions. In addition, pharmacophore key elements might be a group of atoms and a part of the volume of the molecule together with geometrical constraint like distance, angles and dihedral angles [96]. The feature-based pharmacophore models have found extensive use in medicinal chemistry for hit and lead identification and during the subsequent lead to candidate optimization. A 3D pharmacophore is mainly based on the availability of the 3D structure of the binding site of the target. The model can be generated directly from the complex structure of the ligand and the target, according to the 3D structure of the target and a certain number of ligands. Unfortunately, pharmacophore representations cannot explain everything about binding of ligand to the biological target [97]. However, the pharmacophore approach still has proven to be successful, allowing the perception and understanding of key interactions between a target and a ligand.

3.2 Computational methods

3.2.1 HCV NS3/4A protease

3.2.1.1 System preparation and ligand optimization

The three-dimensional structure of ASV in complex with the WT (PDB: 4WF8 and R155K mutant (PDB: 4WH6)) NS3/4A forms [98] was obtained from the protein data bank. The enzyme variant containing the D168A mutation was built by changing residue 168 from aspartate (D) to alanine (A) using the Discovery Studio 2.5 Accelrys Inc. [99]. The apo proteins were generated in all variants by removing the ligand from the complex structure. The protonation state of all ionizable residues was characterized using PROPKA3.1 [100] at pH 7.0. Note that, the cysteine (C) residue that is coordinated with Zn^{2+} was set as deprotonated state (CYM). The missing hydrogen atoms were added using the Leap module [101] in AMBER14 [102]. The electrostatic potential charges of the ligand were computed at the HF/6-31(d) level of theory, while the restrained ESP charges and corresponding parameters of the ligands were generated using the antechamber and parmchk modules, respectively, in AMBER14 [79, 103, 104]. The AMBER ff03.r1 and GAFF force fields were applied for protein and ligand, respectively. Chloride ions were added for neutralizing the simulated systems. Each complex was solvated in a $80.9 \times 69.5 \times 77.9 \text{ \AA}^3$ rectangular box of TIP3P water [105]. The distance between protein and solvation box edge was 10 \AA . Prior to perform the MDSs, the added hydrogen atoms and water molecules were minimized with 1500 steps of steepest descents and conjugated gradient. Lastly, the whole system was minimized using the same procedures.

3.2.1.2 Molecular dynamics (MD) simulation

The MD simulations of all systems were performed under a periodic boundary condition in accord with the standard procedures [102]. All covalent bonds involving hydrogen atoms were fixed using the SHAKE algorithm [106]. The cutoff of 10 \AA was

employed for nonbonded interactions, while the particle mesh Ewald summation method [107] was applied for calculating the long-range electrostatic interactions. A Langevin algorithm [108] was used to control the temperature with a collision frequency of 5.0 ps^{-1} for the first 3.5 ns and subsequently changed to 2.0 ps^{-1} . Each system was heated up to 298 K for 200 ps. Afterwards, all simulations, including the enzyme in APO and in CPX, were treated with the NPT ensemble at this temperature and a pressure of 1 atm using the PMEMD module. All systems were simulated for 100 ns at a time step of 0.002 ps [79]. In each system, 500 snapshots were collected every 1 ns of MD simulation. The binding free energy of all systems was performed using the semi-empirical QM/MM-GBSA method compared with MM/GBSA and MM/PBSA [109, 110]. The inhibitor and the two focused residues (155 and 168) were quantum mechanically treated, while the rest of system was performed using molecular mechanics. The per-residue decomposition free energy ($\Delta G_{bind}^{residue}$) based on the MM/PBSA method was performed to investigate the mutated amino acids (residues 155 and 168) associated with inhibitor binding. Additionally, the important motion of the protein in the WT and mutant (R155K and D168A) systems was characterized by PCA using CPPTRAJ module implemented in AMBER14 [102].

3.2.2 HBV reverse transcriptase

3.2.2.1 Homology modeling, system preparation and ligand optimization

Since the 3D structure of HBV-RT has not been available, the HBV-RT domain sequence (positions 349-693 based on NCBI sequence database (AY233278)) was submitted to SWISS-MODEL web-server [111] using a homologous HIV-RT structure (PDB: 4PQU) [112] as a template. Even though sequence alignment of both enzymes (HIV-RT and HBV-RT) showed only 20.9% of identity, the residues in the active site were conserved for these two enzymes. The Ramachandran plot (**Fig. 13**) showed the number of residues in favored and allowed regions of 78.4% and 20.1%, respectively.

Deoxythymidine triphosphate (dTTP), double-stranded DNA and two magnesium (Mg^{2+}) ions were remained in HBV-RT model according to their original orientation in HIV-RT crystal structure (PDB: 1RTD) [113]. The functional substituents of all HIV and HBV drugs were modified from dTTP substrate (PDB: 1RTD) using Discovery Studio 2.5 [114]. The protonation state of all ionizable residues was assigned using PROPKA3.1 [113] at pH 7.0. The missing hydrogen atoms were added using the Leap module [101] implemented in AMBER16 [115]. The electrostatic potential (ESP) charges of ligand were calculated at the HF/6-31(d) level of theory, while the restrained ESP (RESP) charges and corresponding parameters of ligands were computed respectively using antechamber and parmchk modules in AMBER16 [103, 104]. The AMBER force fields ff14S, GAFF2 and OL15 were applied for protein, ligand and DNA, respectively. Sodium ions were added for neutralizing the simulated systems. Each complex was solvated using TIP3P water model [105] in a rectangular box ($92.9 \times 118.9 \times 103.3 \text{ \AA}^3$). The distance between protein and solvation box edge was 10 \AA . with the spacing distance of 10 \AA . Before performing MD simulations, the added hydrogen atoms and water molecules were minimized using 1,500 steps of steepest descents and conjugated gradient. Finally, the same procedures were used to minimize the whole systems.

3.2.2.2 Molecular dynamics (MD) simulations

MD simulations of all systems were performed under periodic boundary condition in according to the standard procedures [115]. SHAKE algorithm [106] was used to fix all covalent bonds involving hydrogen atoms. The cutoff of 10 \AA was applied for non-bonded interactions, while the particle mesh Ewald summation method [107] was used for calculating the long-range electrostatic interactions. Langevin algorithm [108] was employed to control temperature with a collision frequency of 5.0 ps^{-1} for the first 3.5 ns and subsequently changed to 2.0 ps^{-1} . Each system was heated up to 310 K for 1 ns. After that, all systems were treated with *NPT* ensemble at this

temperature and pressure of 1 atm using the Langevin thermostat. All models were simulated until the simulation time reached 200 ns with time step of 0.002 ps [79]. The 2,500 snapshots of each system were collected in every 10 ns along the simulations. The binding free energy was predicted using the semi-empirical QM/MM-GBSA method and classical MM/GB(PB)SA [109, 110]. The inhibitor was quantum mechanically treated, while the rest of system was performed using molecular mechanics without considering entropy. The per-residue contribution free energy ($\Delta G_{bind}^{residue}$) based on the MM/GBSA method was performed to investigate the key binding residue associated with inhibitor binding.

3.2.2.3 Temperature replica exchange molecular dynamics (T-REMD)

All unbound forms of ligand in explicit TIP3P solvent were obtained after minimizing step of the whole system using the same methods as mentioned above. The number of non-interacting copies (replicas) was performed at different temperatures depending on the temperature range and the total number of particles in the system [95, 116]. Only pairs of replicas corresponding to neighboring temperatures were exchanged according to a Metropolis criterion [95, 116]. A pair of replicas (i and j) at neighboring temperatures (n and m) were exchanged with the probability: $P(i,j) = \exp(-\Delta)$, where $\Delta \equiv [\beta_n - \beta_m](E(q[i]) - E(q[j]))$ and $\beta = 1/k_B T$, q is the coordinate vector, E is the potential energy of the system, T is the absolute temperature, and k_B is the Boltzmann's constant. To obtain a suitable temperature of each replica and a uniform exchange probability, the temperatures were selected following to this equation: $T_i = T_0 \exp(ic)$ [95], where T_0 is the temperature of the first replica and c is constant value. We have used $T_0 = 298$ K and $c = 0.0345$, then generated the following sixteen temperatures (16 replicas): 298.0, 308.5, 319.3, 330.5, 342.1, 354.1, 366.5, 379.4, 392.7, 406.5, 420.8, 435.5, 450.8, 466.7, 483.0 and 500.0 K. Before starting the T-REMD simulations, each replica was performed a short simulation

for 2 ns to equilibrate the systems with an individual temperature. The T-REMD simulations were performed in the *NVT* ensemble. The pairs of replicas were exchanged every 5 ps with 40,000 times along the simulation 100 ns. Finally, the trajectories obtained from the 100 ns of each temperature were assigned as the production phase for further characterization of the structural parameters of each ligand.

To determine the probability of the conformations changes of anti-HIV drugs during the simulation, the trajectories were clustered based on structural analyses including the torsional angle (τ), distance (r) and topological angle (θ) between three subunits of compound (a nitrogenous base, deoxyribose sugar ring and triphosphate group). The conformation within a specified cutoff was categorized into the same cluster. The potential energy overlapping of all neighboring replicas was performed to verify the sufficient numbers of replica exchanges between pairs of replicas. The free energy surfaces (FESs) of compound were calculated from the ratio between the τ , r and θ in all conformations of each temperature as following: $\Delta G^T = -RT \log(P_{torsion}^T / P_{angle}^T)$ and $\Delta G^T = -RT \log(P_{torsion}^T / P_{distance}^T)$, where $P_{torsion}^T$, P_{angle}^T and $P_{distance}^T$ are the probabilities of the compound conformations, measured from the structural parameters of the τ , r and θ of three subunits, respectively, at the temperature T .

3.2.2.4 3D Pharmacophore-based screening

7,500 structures of 3TC and ZDV in complex with HBV-RT extracted from last 30-ns MD trajectories were used as a template for 3D pharmacophore-based screening (3D-PBS) using LigandScout 4.2.6 [96, 97]. Prior to perform 3D-PBS, the library of database was generated from DrugBank [117] containing 9,671 drug-like molecules. Note that only approved drugs were focused. The pharmacophore models were built from every two MD trajectories based on chemical diversity containing essential

features such as hydrogen bond (H-bond) donor, H-bond acceptor, hydrophobic and aromatic ring [118-120]. The same pharmacophore models were clustered and one model from each cluster was used as an agent model for screening. Subsequently, the hits identified from DrugBank database were filtered by applying similarity search for 50% of nucleoside-based scaffold. Finally, the obtained screening result was verified by conducting a receiver operating characteristic (ROC) plot. A set of inactive compounds (decoys) was created by mimicking the structures of active molecules obtained from PubChem database [121]. The ROC values were plotted and interpreted the term of sensitivity (true positive rate) and specificity (false positive rate) of screening results.

3.3.4 Cell lines

The actively HBV-producing HepG2.2.15 human hepatoblastoma cell line was obtained from the Center of Excellence in Hepatitis and Liver Cancer, the Faculty of Medicine, Chulalongkorn University.

3.4 Experimental methods

3.4.1 HBV reverse transcriptase

3.4.1.1 Chemical reagents, cell line and culture

The HBV-producing HepG2.2.15 human hepatoblastoma cell line and TDF were obtained from the Center of Excellence in Hepatitis and Liver Cancer, Faculty of Medicine, Chulalongkorn University. The 3TC (#GP6029), d4T (#GP1591), fluxuridine (FdU, #GP4098), trifluridine (TFT, #GE1913) and sofosbuvir (SOF, #GP2923) were purchased from Glentham Life Sciences (UK). The HepG2.2.15 cells were maintained at 37°C under 5% CO₂ in Dulbecco's modified Eagle medium (DMEM) supplement with 10% (v/v) fetal calf serum, 50 mg/ml G418, non-essential amino acid (NEAA) and antibiotics (amphotericin B, penicillin, and streptomycin). The cultured medium was changed every three days.

3.4.1.2 Drug susceptibility assays

Drug stock solutions were prepared freshly in 100% DMSO as 200X stock and three additional 10-fold dilutions were prepared from these stocks. HepG2.2.15 cells were seeded into a 24-well plate at a density of 5×10^5 cells/well. Cells were treated

with different concentrations of drug(s) at days 1 and 3. Finally, cells were harvested on day 7 for real-time PCR (RT-PCR). Experiments were performed in duplicate.

3.4.1.3 Quantification of HBV DNA using real-time PCR and cytotoxicity assay

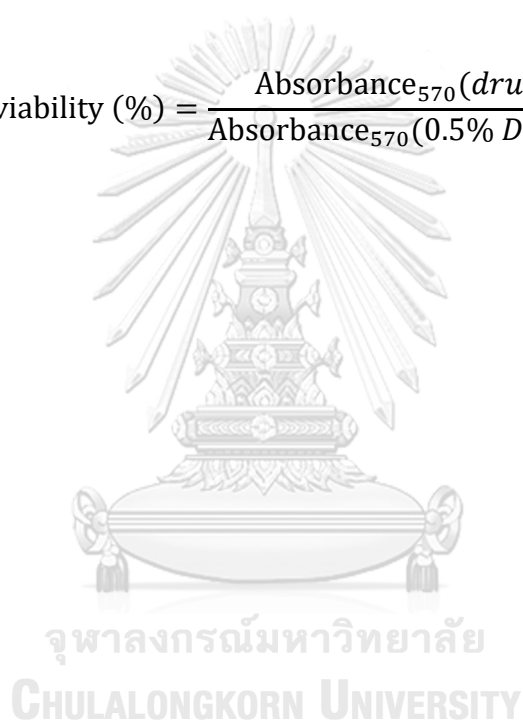

For RT-PCR, cellular DNA in HepG2.2.15 cells was extracted using GenUP™ gDNA Kit from biotechrabbit according to the manufacturer's instructions. Briefly, 1 ml of HBV DNA samples were amplified using 2X SYBR green PCR master mix (biotechrabbit) with the following primers for detecting intrahepatic HBV DNA: 5'-TCCTCCAAYTTGCTCCTGGTYATC-3' and 5'-AGATGAGGCATAGCAGCAGGAT-3' and for HBsAg gene and (ii) 5'-GTGCACCTGACTCCTGAGGAGA-3' and 5'-CCTTGATACCAACCTGCCCCAG-3' for β -globin gene. The PCR preparations of intrahepatic HBV DNA were incubated at 95°C for 3 minutes, followed by 50 cycles with 95°C for 15 seconds, 55°C for 20 seconds and 72°C for 30 seconds, and 60°C for one minute. Note that for β -globin, the annealing step was set as 58°C for 20 seconds instead. The data were analyzed using StepOne™ Software Version 2.1 (Applied Biosystems) and threshold cycle (C_T) values were obtained. To calculate copy numbers of HBsAg gene out of C_T values, a standard curve was generated with 7-fold serial dilutions of an HBV plasmid (pHBV^{WT}; 10^3 to 10^9 copies per reaction) and 7-fold serial dilutions of a β -globin plasmid (10^3 to 10^9 copies per reaction), and the C_T values for each sample were converted into HBV copy numbers. The HBV DNA inhibition activity was calculated as:

$$\text{The HBV DNA inhibition activity (\%)} = \frac{\text{Copy number}_{\text{HBsAg}}}{\text{Copy number}_{\beta\text{-globin}} \times S} \times 100$$

where S is the ratio of the copy number between HBsAg and β -globin of vehicle control (0.5% DMSO). Cell viability was assessed using the MTT assay. HepG2.2.15 cells were

plated in a 96-well plate at a density of 4.5×10^4 cells/well. After overnight incubation, cells were treated with various concentrations of a compound (1 μM to 100 μM) at days 1 and 3. After 7 days of incubation, the MTT solution (0.5 mg/mL) was added and incubated for another 1 hour. The medium was removed and 150 μL of DMSO was added to each well. The cell viability was detected by measuring the absorbance at a wavelength of 570 nm using spectrophotometer (Thermo Fisher Scientific Oy, Finland). The cell viability was calculated according to the following equation:

$$\text{Cell viability (\%)} = \frac{\text{Absorbance}_{570}(\text{drug})}{\text{Absorbance}_{570}(0.5\% \text{ DMSO})} \times 100$$

CHAPTER IV

RESULTS AND DISCUSSION

4.1 HCV NS3/4A protease

4.1.1 Stability of the global structure of each simulated model

The all-atom root-mean-square displacement (RMSD) was calculated in order to estimate the stability of each simulated model (WT and the R155K and D168A single point mutations in APO and in CPX with ASV) along the simulation time. As shown in **Fig. 6**, the RMSD value of each system rapidly increased during the first 10 ns and then fluctuated at ~ 2.2 - 2.7 Å in all the studied models until the end of the simulations. Altogether, the MD simulation systems tended to be stable after 60 ns. In this study, the equilibrated MD simulation trajectories extracted from the last 15 ns were used for further analysis of the *(i)* electrostatic network at the mutation site, *(ii)* protein conformation, *(iii)* inhibitor-protein hydrogen bond (H-bond) interaction and *(iv)* effect of mutations on the inhibitor binding affinity.

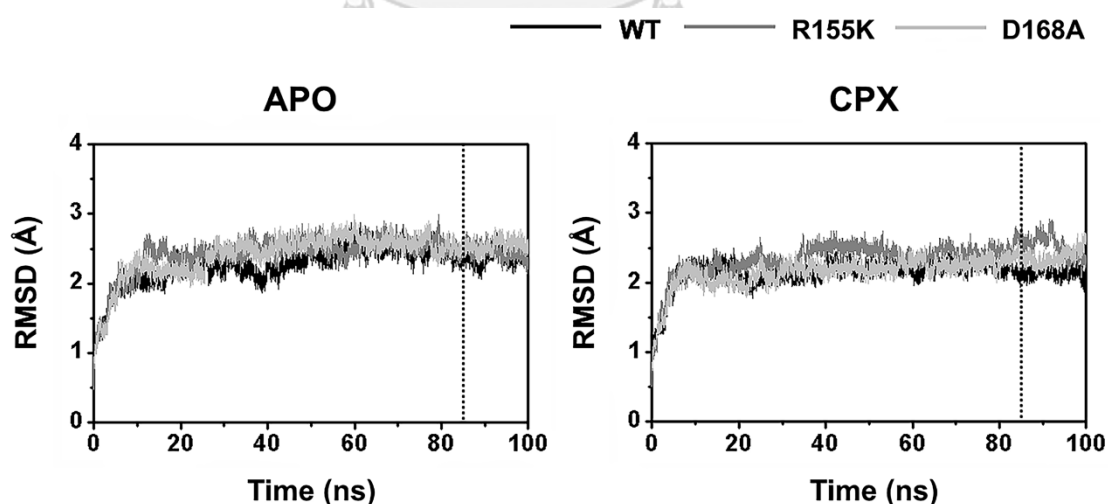

Figure 6 RMSD plots of the WT (black), R155K (grey) and D168A (light grey) HCV NS3/4A protease without (APO) and with (CPX) ASV binding for 100 ns of MD simulation

4.1.2 Electrostatic network at the mutation site

It has been reported that the electrostatic network formed at residues R123---R155---D168 plays an important role in the inhibitor binding [122]. In order to calculate this interaction network throughout the production phase of the simulation, we used the geometric criteria of: (i) a distance between the H-bond donor and acceptor of $\leq 3.5 \text{ \AA}$ and (ii) a H-bond angle of $\geq 120^\circ$. As shown in **Fig. 7**, a high percentage of H-bond occupation ($\%HB_{oc}$) was detected in the WT system in both the APO and CPX. As expected, the R155K and D168A point mutations importantly decreased the electrostatic network formation compared to that of the WT NS3/4A, resulting in a lower binding affinity of ASV towards R155K and D168A NS3/4A. The point mutations decreased not only the electrostatic attractions but also the van der Waal (vdW) interactions, indicating that vdW forces also played a role in the drug binding (**Fig. 8**). The obtained results strongly agreed with previous reports [100, 105] as well as our QM/MM-GBSA free energy calculation (as discussed later and **Fig. 12**)

4.1.3 Protein conformation

To understand the effect of the R155K and D168A mutations on the protein conformational changes, PCA was performed [123]. These motions correspond to the correlated vibration or collective motion of groups of atoms. The scatter plots between the first (PC1) and second (PC2) principal components indicated the different distribution of protein conformations.

The PCA scatter plots (**Fig. 9A**) revealed that the conformational distributions of the holo (CPX) form of both mutations were dramatically different from those of the WT, implying that the R155K and D168A mutations in NS3/4A promoted protein conformational changes in a contrasting manner, which can significantly affect the protein-ligand binding affinity (**Fig. 12**, as discussed later). The first 15 PC modes of all studied models in the CPX and APO forms showed a percentage of accumulated

variance of >50%, indicating that these modes represent the important motions of protein (Fig. 9B).

Figure 7 H-bond network of the three important NS3 residues (R123, R155 and D168) in the WT, R155K and D168A systems in both APO and CPX forms.

According to the porcupine plot of the WT system (Fig. 10, top), the direction of motion of residues R123, R155 and D168 moved towards the ligand binding, in a different manner from that in the APO form, suggesting that ligand binding induces the closed form of the protein, in which these three residues are important for ASV recognition. Additionally, the ligand interacted firmly in the pocket site due to the long side chains of two arginine residues. As expected, both R155K and D168A mutations caused the key binding residues 123, 155 and 168 to significantly move outwards from

ASV, resulting in a loss of electrostatic attractions and H-bond interactions. In summary, these structural transformations could be the reason why ASV showed a low susceptibility towards the R155K and D168A forms of the NS3/4A protease.

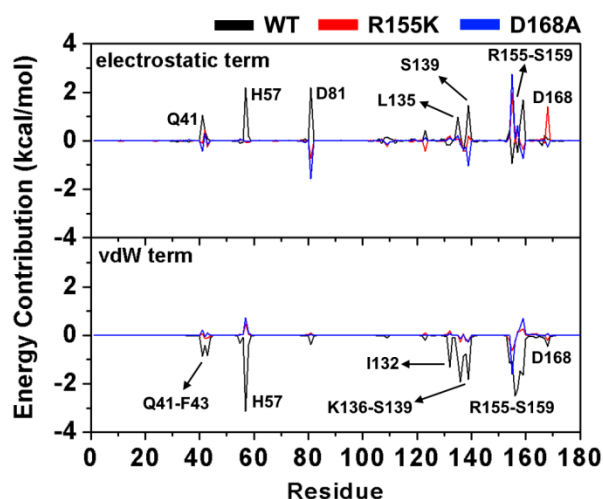

Figure 8 Averaged electrostatic and vdW energy contribution from each residue of NS3 protease domain in WT and mutant forms.

4.1.4 Inhibitor-protein H-bond interaction

One of the important factors involved in the stabilization of protein-ligand complexes is H-bonds. To measure such interactions throughout the overall simulation and equilibration phase (the last 15 ns), H-bond formation was calculated using the two geometric criteria described above, and the results are shown in **Fig. 11**. Among the five sites of ASV (P1' and P1-P4, **Fig. 2A**), there were no H-bond interactions between the NS3/4A protease and ASV at the P2 and P4 moieties, in accord with the previous report on faldaprevir and danoprevir recognition [124]. For the WT NS3/4A (black), ASV showed 4 strong H-bonds ($\%HB_{oc} > 70$), one each with G137 and R155 at the P1' and P1 site, respectively, and two with A157 at the P3 site. With two firm H-bonds detected at the P3 site, the A157 residue played an important role as recognition site for anti-HCV protease inhibitors (**Fig. 11A**) [79]. Notably, the number of H-bonds formed in the mutated NS3/4A, especially R155K, was lower than those in the WT, suggesting that

these mutations attenuate the H-bonds, which is consistent with the loss of electrostatic network formation detected in the R155K and D168A mutations (Fig. 11B).

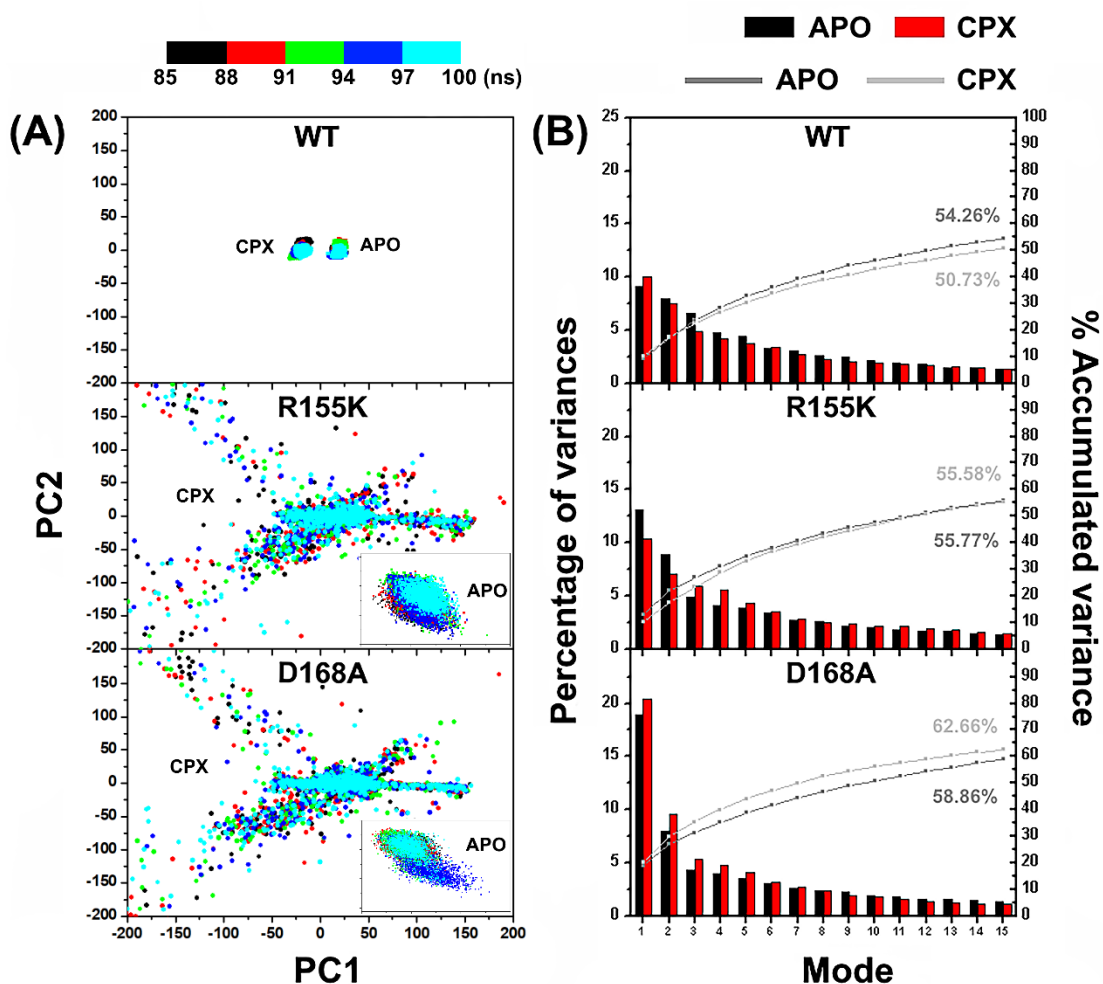

Figure 9 (A) The two-dimensional scatter plot of MD simulation trajectories between the first (PC1) and second (PC2) principal components. (B) The PCA scree plot of quantitative characters of the first 15 modes.

4.1.5 Effect of the R155K and D168A mutations in NS3/4A on the ASV binding affinity

To evaluate and compare the binding affinity of ASV against the WT and the R155K and D168A mutant strains of the NS3/4A protease, the QM/MM-GBSA binding free energy calculations were performed on 100 snapshots extracted from the last 15

ns of each MD simulation. Based on this approach, the ASV inhibitor and the NS3/4A residues 155 and 168 were treated by the semiempirical methods (AM1, RM1, PM3 and PM6) compared with MM/GBSA and MM/PBSA, while the remainder was described at the MM level. The results of the averaged binding free energies in each system are compared in **Fig. 12**, which demonstrated that the binding free energy ($\Delta G_{bind}^{residue}$) values obtained from all four levels of QM theory are in the same order of WT > R155K > D168A. The R155K and D168A single point mutations resulted in a significant reduction in the binding free energy by ~6 and ~9 kcal/mol, respectively, compared to the WT complex, in reasonable agreement with the experimentally observed 21- and 23-fold changes in the EC_{50} values, respectively. Unlike QM/MM-GBSA method, the free energy values between WT and both mutations obtained from MM/GBSA and MM/PBSA calculations were not significantly different. In addition, it should be noted that the calculated binding free energy does not give us an absolutely accurate binding free energy value in comparison with experimental data, but it evidently shows a relative binding affinity between WT and mutant strains toward ASV. Moreover, EC_{50} values which refer to concentration of a drug that causes the half maximal effect of an observed effect cannot directly compare to the binding efficiency of drug toward targeted protein.

Figure 10 Porcupine plot of the PC1 of the studied systems. The arrow head and its length indicate the direction and amplitude of motions, respectively.

Moreover, the QM/MM-GBSA binding free energy calculations results were similar to previous computational studies, where the binding affinities of narlaprevir and vaniprevir towards the NS3/4AR155K mutant were significantly lower than that of the WT strain [125, 126], while the D168 A/V mutants of NS3/4A considerably decreased the susceptibilities of faldaprevir, danoprevir and vaniprevir [124, 125]. In summary, our QM/MM-GBSA binding free energy calculations not only supported the role the R155K and D168A mutations towards the weaker binding affinity of ASV, but

also strongly predicted the susceptibility of this inhibitor in same manner as the experimental data.

Figure 11 **A)** Percentage of H-bond occupation over the last 15 ns, and **B)** the number of H-bond (versus simulation time) of NS3 residues formed with ASV in the WT and the R155K and D168A mutant forms of NS3/4A.

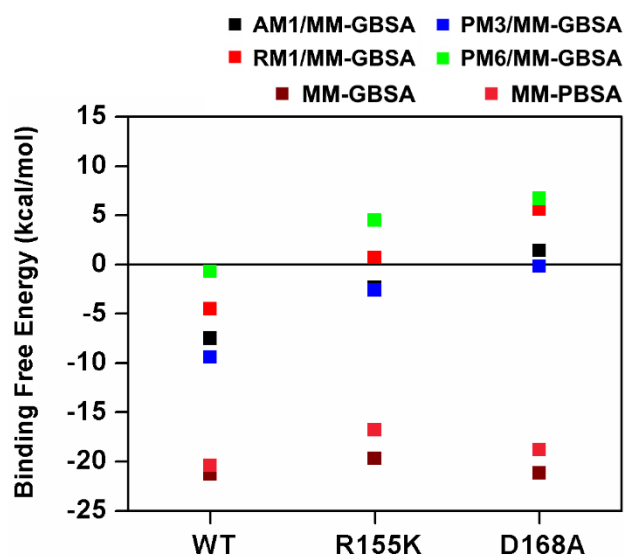

Figure 12 Binding free energy calculated by the MM/GBSA, MM/PBSA and the QM/MM-GBSA method, at the AM1 (black), RM1 (red), PM3 (blue) and PM6 (green) levels of QM theory for the WT and R155K/D168V mutant systems.

4.2 HBV reverse transcriptase

4.2.1 System stability of global structure

The root-mean-square displacement (RMSD) of residues around 5 Å of ligand in the active site was calculated to estimate the stability of all simulated models along the simulation times. As shown in **Fig. 14**, the RMSD value of protein residues in the active site of each system rapidly increased during the first 10 ns and then fluctuated at ~2.0-3.5 Å for all studied models until the end of the simulations. In contrast, the RMSD fluctuations of ligand were much less than those of protein by ~0.5-2.0 Å (except 3TC system). In the present study, the equilibrated MD simulation trajectories extracted from the last 30 ns were extracted for further analysis in terms of: the (i) key binding and drug-protein interactions, (ii) ligand topology, (iii) binding affinity of anti-HIV drugs against HBV-RT and (iv) virtual screening based on 3D-PBS.

Figure 13 The Ramachandran plot of HBV-RT model which was modeled from HIV-RT.

4.2.2 Key binding and drug-protein interactions

The important amino acid residues involved in drug binding were characterized using $\Delta G_{\text{bind}}^{\text{residue}}$ calculation based on MM/GBSA method (Fig. 15). Note that the negative and positive values of the energy contribution correspond to the energy stabilization and destabilization, respectively. From the fingerprint of all systems with energy stabilization of ≤ -2 kcal/mol, the results demonstrated that there were seven polar residues (K32, R41, D83, S85, D205, N236 and K239) and three hydrophobic moieties (A86, A87 and F88) associated with drug binding. These results suggested that electrostatic attraction is the main force inducing protein-ligand complexation, which is consistent well with MM calculations (Table 1). The energy destabilization at D83

and D205 residues was occurred by the repulsion of negative charge between aspartic acid residues of HBV-RT and the phosphate groups of ligands.

Figure 14 RMSD plots of residues around 5 Å from ligand in active site of HBV-RT (black) and ligand (grey), anti-HBV and anti-HIV drugs, systems for 200 ns of MD simulations

In order to support the role of Mg^{2+} as a cofactor, the $\Delta G_{\text{bind}}^{\text{residue}}$ of HBV-RT toward Mg^{2+} ions was calculated, and the obtained results (Fig. 16) revealed that two Mg^{2+} played an important role in stabilizing HBV-RT at D83 and D205 residues. Apart from amino acids residues, the double-stranded DNA, especially at 3'OH of nitrogenous

base, also contributed against ligand binding with the $\Delta G_{\text{bind}}^{\text{residue}}$ of ~ -1 to -4 kcal/mol (Fig. 17). One of the important factors involving in the stabilization of protein-ligand complexes is H-bonds. To measure such interactions throughout the equilibration phase, H-bond formation was calculated using the two geometric criteria: (i) the distance between the H-bond donor and H-bond acceptor of ≤ 3.5 Å and (ii) the H-bond angle of $\geq 120^\circ$ (weak H-bond, Fig. 18A) and $\geq 150^\circ$ (strong H-bond, Fig. 18B). The obtained results showed that the H-bond formations were highly detected in ZDV system, especially R41 and S85 residues (Figs 18A-B). On the other hand, the DDI showed the lowest H-bonds (for both weak and strong H-bonds criteria) as compared with the other anti-HIV drugs. In the case of d4T, there were two firmly strong H-bonds detected at A86 and A87 residues, which are somewhat similar to the 3TC. Interestingly, the HBV-RT residues K32, A86, A87 and N236 could form several H-bond interactions with ligands rather than other amino acids, suggesting that these four residues are important recognized sites for ligand binding, which is in accord with the $\Delta G_{\text{bind}}^{\text{residue}}$ calculations (Fig. 15) and H-bond analysis from previous report [127].

Altogether, the obtained drug-protein interactions suggested that (i) the energy stabilization for drug binding not only came from protein target but also derived from the adjacent DNA molecules and (ii) electrostatic attractions and H-bond formations were the crucial interactions associated with drug binding

Table 1 MM calculations of anti-HBV and anti-HIV drugs for binding with HBV-RT based on MM/GBSA method.

Energy (kcal/mol)	Simulated system				
	dTTP	3TC	d4T	DDI	ZDV
ΔE_{vdW}	-23.13 ± 0.45	-18.89 ± 0.53	-17.92 ± 0.62	-15.73 ± 0.57	-21.07 ± 0.61
ΔE_{ele}	-622.46 ± 4.95	-394.17 ± 4.65	-670.69 ± 4.26	-360.51 ± 4.57	-659.71 ± 5.93
ΔE_{MM}	-645.59 ± 4.96	-413.07 ± 4.59	-688.61 ± 4.18	-376.24 ± 4.63	-680.78 ± 5.92

Figure 15 The per-residue contribution free energy of HBV-RT for dTTP, 3TC, d4T, DDI and ZDV in which energy contribution values are labeled from purple to black with -8 kcal/mol to 12.0 kcal/mol.

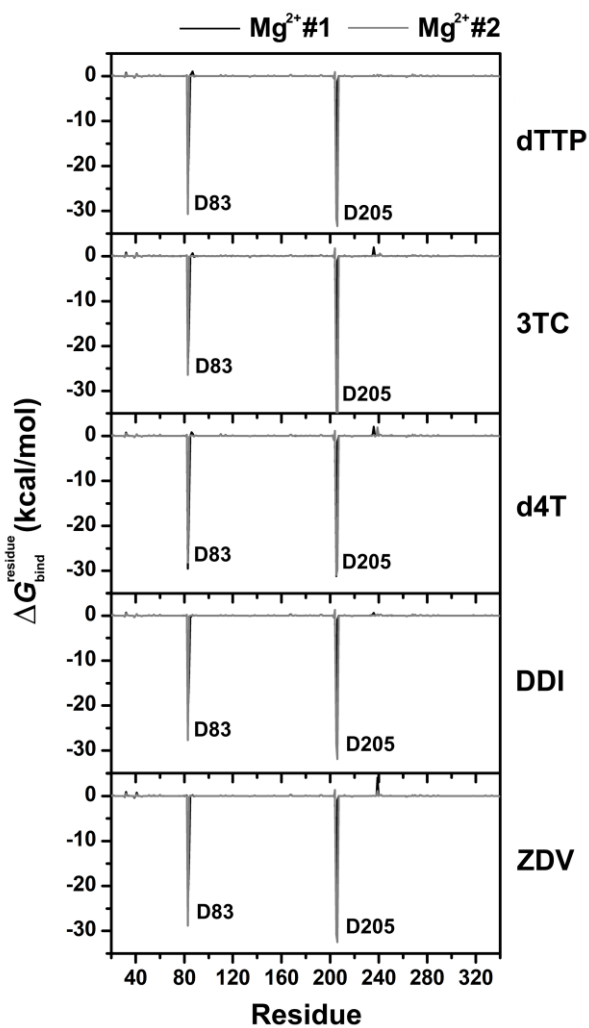

Figure 16 Averaged total energy from each residue of HBV-RT domain with Mg^{2+} in all systems.

4.2.3 Ligand topology

To characterize the conformation of HIV (d4T, DDI and ZDV) and HBV (3TC) drugs as well as HBV substrate (dTTP) in complex with and without HBV-RT, the structural parameters τ , r and θ (Fig. 5C) were calculated and plotted as the probability distribution over the production phase at 310 K. In addition, the representative snapshots extracted from T-REMD simulation are illustrated in Fig 19B. According to the canonical probability distributions (Fig. 20), there were enough overlaps between

all neighboring pairs of distributions in all systems, indicating the sufficient numbers of replica exchanges between pairs of replicas.

Figure 17 The per-residue decomposition free energy of double-strand DNA which in complex with HBV-RT for dTTP, 3TC, d4T, DDI and ZDV.

The τ and θ structural parameters were chosen to construct the FES profile (Fig. 19). In the case of unbound state, the distribution of τ of all ligands showed similar patterns (except d4T) in which the populations of τ and θ were mostly found at -180° , 60° and 180° and at 60° to 180° , respectively. By considering d4T system, the local

minima detected at τ of $\sim 60^\circ$ and at θ of $\sim 60^\circ$ to 120° was similar to that of ZDV. In addition, the DDI showed an almost identical conformational pattern with 3TC at the θ of -180° , 60° and 180° . As shown in **Fig. 21**, the distribution of r showed the similar trend with that of θ for both bound- and unbound states, in which only one population was detected (~ 5 to 13 \AA for r (**Fig. 21**) and $\sim 60^\circ$ to 180° for θ (**Fig. 19**)). As expected, the FESs of ligands conformations in bound state were more negative than those of unbound ones, as evidenced by the obviously increased blue color, indicating that the protein-ligand complexation promoted the stable conformation of ligands.

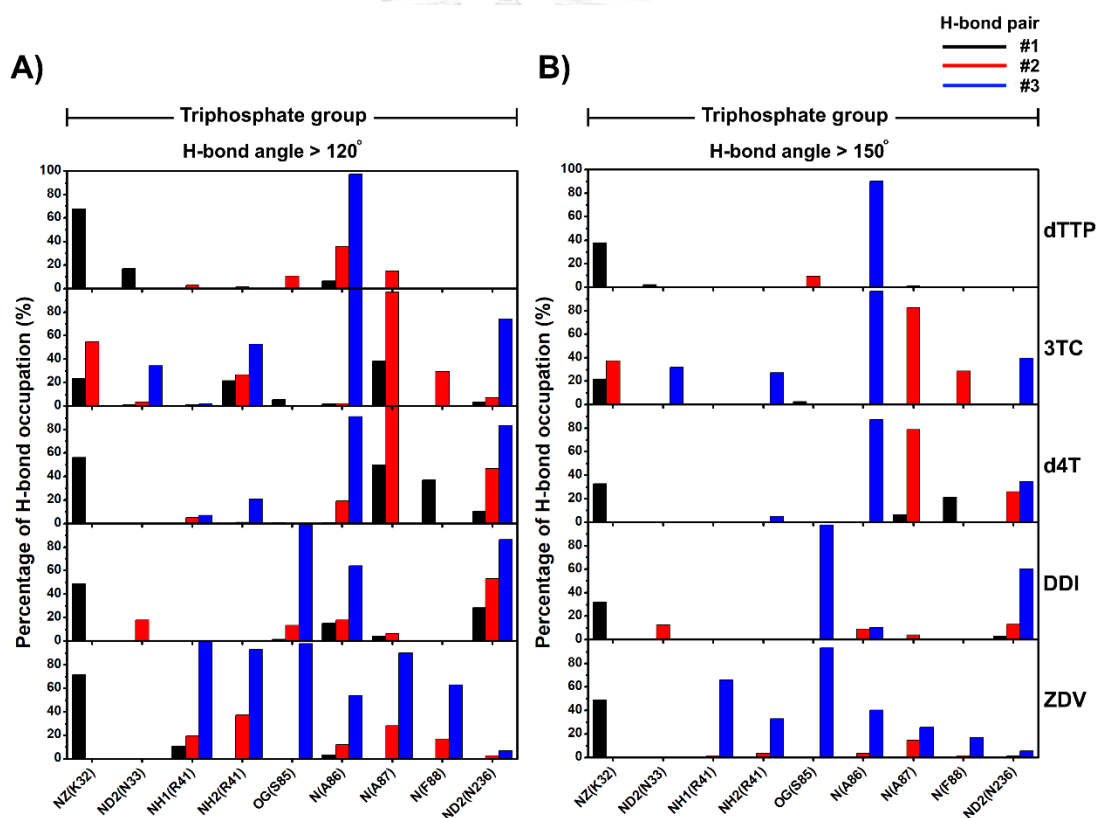

Figure 18 The H-bond occupation of HBV-RT formed with five ligands over 30 ns. **A)** Weak H-bond formation was calculated using angle $\geq 120^\circ$. **B)** Strong H-bond calculated using $\geq 150^\circ$. Each detected H-bond interaction was represented in black, red and blue.

Figure 19 **A)** FES map of dTTP, 3TC, d4T, DDI and ZDV showing the distribution of τ and θ in unbound and bound forms at 310.0 K. The FESs (kcal/mol) were ranged from 0 (grey) to -3.5 kcal/mol (black). **B)** The representative conformation of ligand in bound (green) and unbound (blue) states.

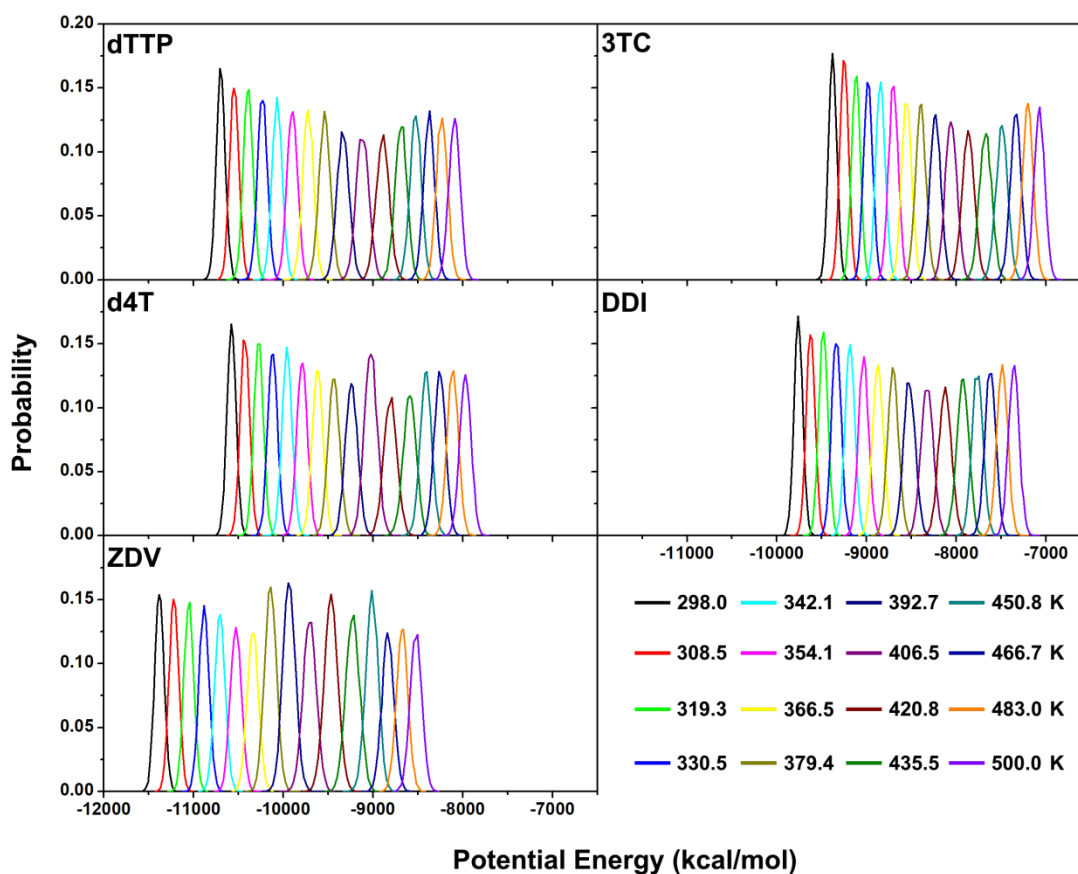

Figure 20 The probability distributions of the total potential energy of all ligands in all temperatures (replicas). Each temperature is represented in different colors.

4.2.4 Binding affinity of anti-HIV drugs against HBV-RT

The susceptibility of anti-HIV drugs against HBV-RT was predicted using the QM/MM-GBSA and MM/GB(PB)SA binding free energy (ΔG_{bind}) calculations on 100 snapshots extracted from the last 30 ns of each MD simulation. Based on QM/MM-GBSA, all drugs were treated by the semiempirical methods (AM1 and PM6), while the remainder was described at the MM level. Note that (i) the binding free energies were calculated without considering entropy and (ii) The QM/MM-GBSA and MM/GB(PB)SA calculations provided the same trend.

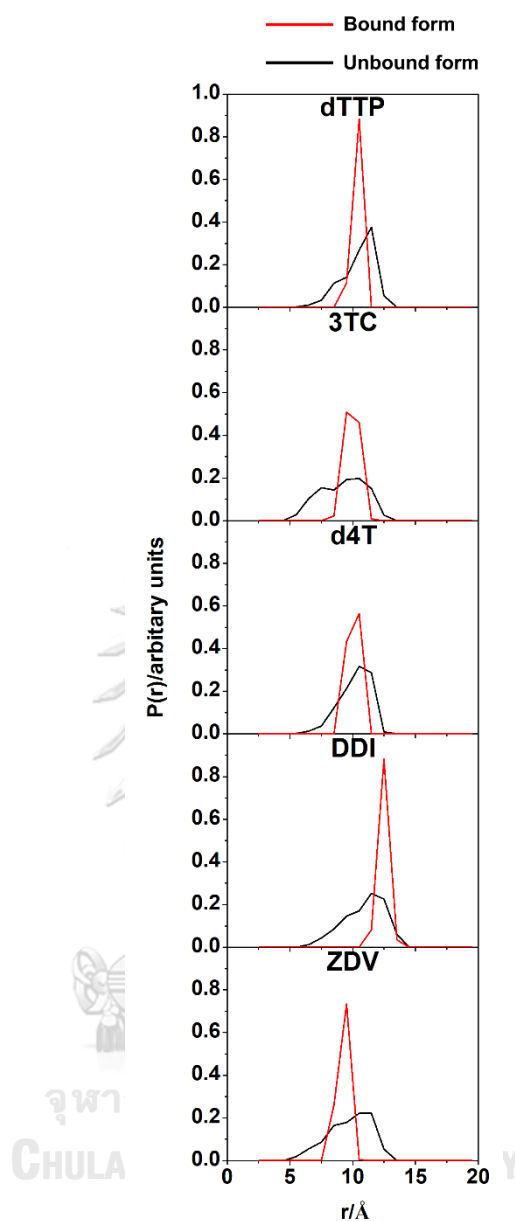

Figure 21 Distribution of distance (r) of dTTP, 3TC, d4T, DDI and ZDV in unbound and bound form with HBV-RT at 310.0 K.

The obtained results (Fig. 22) demonstrated that the ΔG_{bind} values of anti-HIV drugs obtained from all methods were in the same order of $ZDV < d4T \ll DDI$. The binding affinity of d4T and ZDV drugs was higher than those of dTTP substrate, which is in good agreement with previous study demonstrating that the binding strength of anti-HBV drug tenofovir towards the HBV-RT was higher than that of dATP substrate

[61]. Although ZDV showed the highest affinity against HBV-RT (Fig. 5) and could potentially inhibit HBV-RT activity with the IC_{50} of 0.3 μ M, the *in vivo* and clinical study results indicated that ZDV remains ineffective. Hence, d4T was chosen instead for further *in vitro* studies.

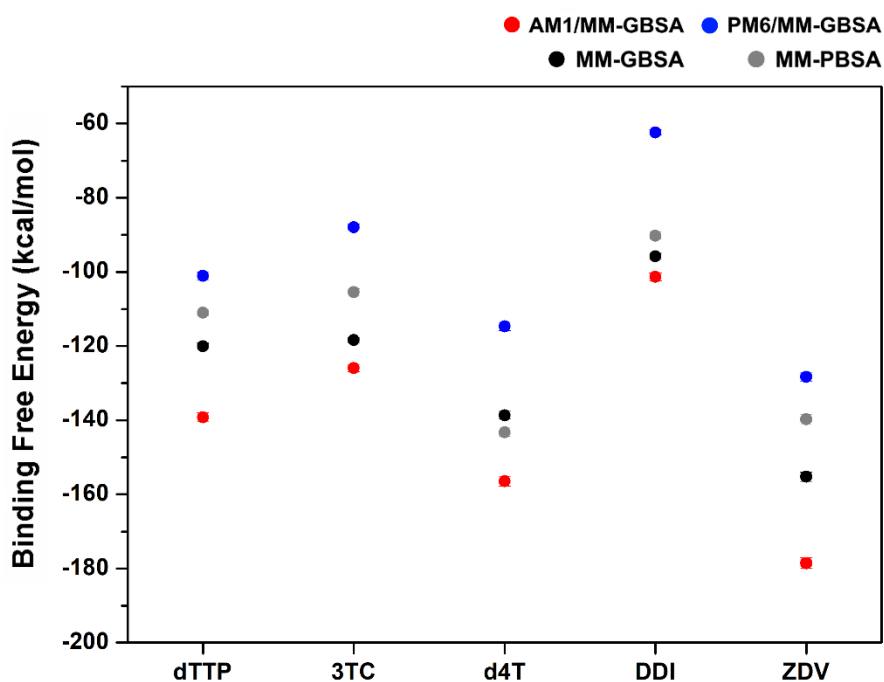

Figure 22 The predicted binding free energies of anti-HIV drugs compared with the substrate and anti-HBV drug to HBV-RT using QM/MM-GBSA and MM/GB(PB)SA calculations.

4.2.5 Virtual screening based on 3D pharmacophore modeling

To identify the new potent candidates against HBV-RT, the 3D-PBS was applied. First, only 2,329 approved drugs were selected from DrugBank database. After that, these compounds were filtered and collected by applying the respectively 3D-PBS (using pharmacophore features: H-bond donor (green arrow), H-bond acceptor (red arrow) and hydrophobic interaction (yellow sphere) (Fig. 23)) and similarity search for 50% of nucleoside-based scaffold; as a result, only 16 screened compounds were obtained. Subsequently, the anti-HBV, anti-HIV and other drugs, which already tested with HBV (e.g., zidovudine, telbivudine, stavudine, didanosine, tegafur and Isoprinosine)

[128-130], were removed from such 16 compounds, remaining only 10 drugs left as shown in **Table 2**. Finally, three of them, including floxuridine (FdU, an anti-cancer drug) [131], trifluridine (TFT, an anti-herpesvirus drug) [132], sofosbuvir (SOF, a high molecular weight drug) [133] were selected as representative compound for *in vitro* HBV DNA inhibition assay.

The performance of 3D-PBS and the ability of identifying the structural similarity between (i) 4,583 decoys and 10 active compounds for 3TC and (ii) 3,583 decoys and 10 active compounds for ZDV were determined using the receiver operating characteristic (ROC) plot, where the area under the curve (AUC) indicates the quality of ROC plot. The AUC value of > 0.50 indicated that the active molecules are reliable. As shown in **Fig. 24**, the AUC values are 0.50 (1%), 0.90 (5%), 0.95 (10%), and 0.91 (100%) for the 3TC and 1.00 (1%), 1.00 (5%), 1.00 (10%), and 0.77 (100%) for the ZDV; thus, the hit compounds derived from 3D-PBS are acceptable. Altogether, FdU, TFT and SOF, obtained from 3D-PBS, and the d4T, acquired from free energy calculations, were then examined for their anti-HBV activity *in vitro*.

Figure 23 The screening workflow based on 3D-PBS and similarity search for 50% of nucleoside-based scaffold.

4.2.6 *In vitro* Inhibition of HBV replication

To evaluate the anti-HBV activity of anti-HIV drug (d4T) and the screened compounds (FdU, TFT and SOF) in comparison with anti-HBV drugs (TDF and 3TC), HepG2.2.15 cells expressing HBV were treated with all focused compounds at different concentrations of 1 μM , 10 μM and 100 μM for 7 days. Note that (i) the HepG2.2.15 cells intracellularly contain HBV DNA in both forms: integrated- and episomal DNAs and (ii) the amount of integrated DNA was not affected by the addition of anti-HBV agents, while the episomal DNA would be decreased if the HBV-RT is inhibited.

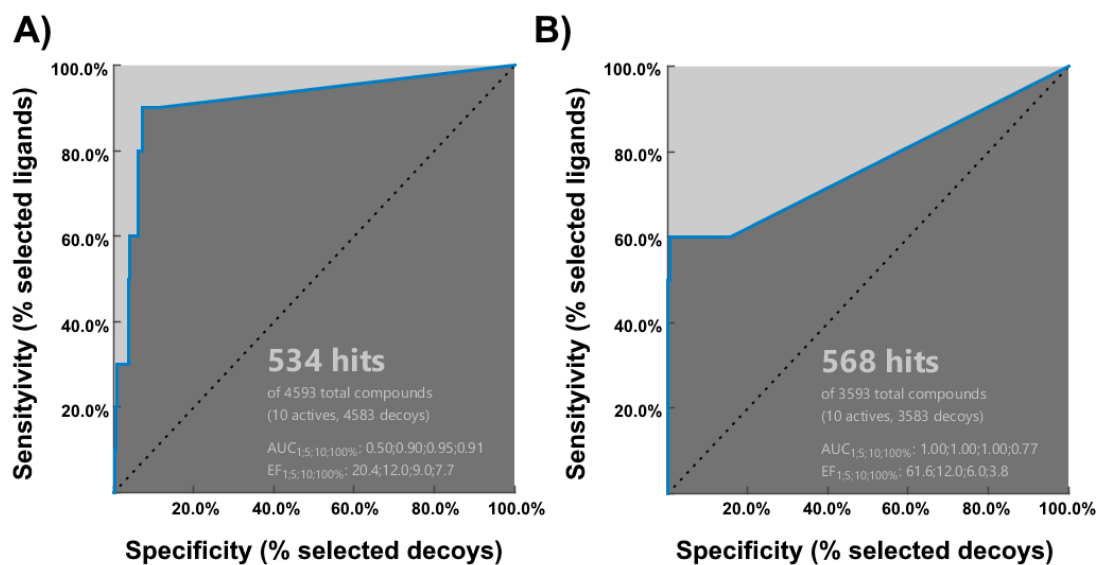

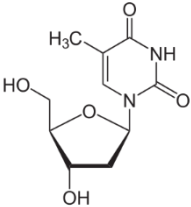

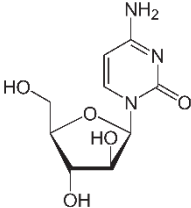

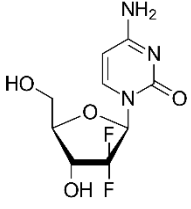

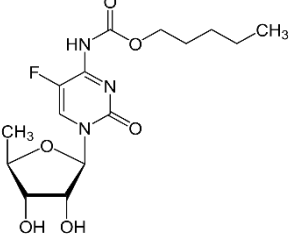

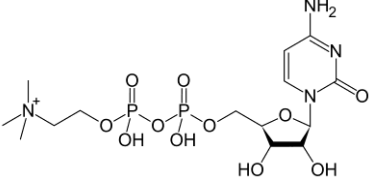

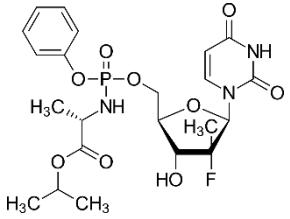

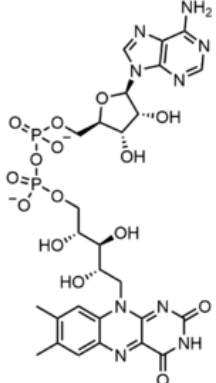

Figure 24 ROC plot of 3D-PBS applied on HBV-RT with **A)** 3TC and **B)** ZDV. The enrichment factor (EF) and the AUC are given for 1, 5, 10, and 100% of database.

Table 2 List of 10 screened compounds obtained from similarity search for 50% of nucleoside-based scaffold and the removal of HIV/HBV drugs.

Name	Target	M.W.	2D structure
Anti-herpesvirus drug			
Trifluridine (TFT)	- Primary keratoconjunctivitis - Recurrent epithelial keratitis	296.20	
Idoxuridine	- Herpes simplex keratitis	354.10	
Brivudine	- Varicella zoster virus which causes herpes simplex virus type 1	333.13	

Anti-cancer drug			
Floxuridine (FdU)	- Colorectal cancer	246.19	
Cytarabine	- Acute myeloid leukemia (AML) - Acute lymphocytic leukemia (ALL) - Chronic myelogenous leukemia (CML)	243.21	
Gemcitabine	- Breast cancer - Ovarian cancer - Non-small cell lung cancer - Pancreatic cancer - Bladder cancer	263.20	
Capecitabine	- Breast cancer - Gastric cancer - Colorectal cancer	359.35	
High molecular weight drug (M.W >400)			
Citicoline	- Alzheimer's disease - Other types of dementia, head trauma and cerebrovascular disease	488.32	
Sofosbuvir (SOF)	- Hepatitis C virus (HCV)	529.46	

FAD	- An ophthalmic treatment for vitamin B2 deficiency	785.55	
-----	-----------------------------------------------------	--------	-------------------------------------------------------------------------------------

The *in vitro* HBV DNA inhibition assay (**Fig. 25A**) revealed that anti-HIV drug d4T, which was obtained from free energy calculations, displayed good anti-HBV activity (~25%) at 1 μM , whereas the activity of this drug was dramatically decreased at higher concentrations (10 and 100 μM). This finding likely suggested that acquired drug resistance might be occurred at high doses. Interestingly, our screened drug FdU, derived from 3D-PBS, showed the highest anti-HBV activity (~10-20%) and suppressed HBV DNA in a concentration-dependent manner. However, the other two screened drugs (TFT and SOF) did not cause a dramatic decrease in the HBV DNA at all three concentrations; therefore, only FdU was selected to examine the cell viability using MTT assay (**Fig. 25B**).

The MTT results indicated that FdU decrease cell viability by ~40% at all concentrations. As compared to 1 μM HBV drug TDF, the FdU at 1 μM displayed the lower cell viability by ~20%, indicating that FdU can cause the toxicity toward hepatocytes. Taken together, FdU could possibly reduce the HBV DNA but still had toxicity; thus, the reduction of HBV DNA might partly come from cell death. Unfortunately, the cell based assay was the indirect inhibition for inhibiting RT, indicating that the inhibition activity of 3TC and d4T might come from other factors such as the ability to transport medicines into cells or the environment of cells. To evaluate the drug activity against HBV-RT, the enzyme assay was the one choice for direct inhibition, which the results would agree with binding free energy calculation.

Hence, the enzyme assay was an interesting method for further testing the ant-HIV drug against HBV-RT.

Figure 25 **A)** Inhibition activity of HBV DNA in HepG2.2.15 cells with TDF, 3TC, d4T, FdU, TFT and SOF. Cells were treated with 1, 10 and 100 μM of each drug. **B)** Effect of FdU on HepG2.2.15 cell viability. The number of viable cells was determined using MTT assay. Data are expressed as mean ± SD of two independent experiments.

CHAPTER V

CONCLUSION

5.1 HCV NS3/4A protease

In this work, 100-ns MD simulations were applied on the WT and on the R155K and D168A single point mutations of the NS3/4A protease in the apo form and in complex with ASV, a current drug in phase III clinical trials. According to the PCA, these two mutations dramatically converted the direction of motion of the key binding residues (123, 155 and 168) to move outwards from ASV, resulting in a loss of electrostatic attraction and H-bond formation. The QM/MM-GBSA binding free energy calculations at different levels of QM theory (AM1, RM1, PM3 and PM6) suggested that both mutations caused a significant reduction in the binding affinity, ranked in the order of WT < R155K < D168A, which agreed with the observed experimental EC₅₀ values. In addition, it can be postulated that other related mutations might have a similar pattern in drug binding and the loss of interactions like in our cases present here. Consequently, our findings can allow us to predict the effect of mutations on the binding affinity at least without simulations. Taken together, the theoretically obtained information can be used as a rational guide for antiviral drug design and development towards the HCV genotype 1, which is the most prevalent genotype worldwide.

5.2 HBV reverse transcriptase

In this work, 200-ns MD simulations were performed on the HBV-RT in complex with dTTP substrate, anti-HBV drug (3TC) and three anti-HIV drugs (d4T, DDI and ZDV). According to the QM/MM-GBSA and MM/GB(PB)SA binding free energy calculation, the binding affinity of anti-HIV drug d4T was significantly higher than that of anti-HBV drug 3TC, suggesting that d4T could possibly inhibit this HBV-RT. The calculations of FESs revealed that the ligand conformations in bound form were more stable than those

of unbound state. Based on 3D-PBS and *in vitro* anti-HBV activity, the obtained FdU could possibly reduce the intrahepatic HBV DNA. However, this drug still had toxicity toward hepatocytes. Altogether, the obtained information can be used as a rational guide for designing and developing a novel derivative of FdU to diminish its cytotoxicity.

APPENDICES

จุฬาลงกรณ์มหาวิทยาลัย
CHULALONGKORN UNIVERSITY

APPENDIX B

H-bond orientation of anti-HIV and anti-HBV drugs in complex with HBV-RT taken from the last MD snapshot.

APPENDIX C

A standard curve of A) a HBV plasmid (pHBV^{WT}) with 7-fold serial dilutions (10^3 to 10^9 copies per reaction) and B) a β -globin plasmid with 7-fold serial dilutions (10^3 to 10^9 copies per reaction)

VITA

NAME Jirayu Kammarabutr
DATE OF BIRTH 18 July 1993
PLACE OF BIRTH Bangkok, Thailand
INSTITUTIONS ATTENDED Chulalongkorn University
HOME ADDRESS 1044 / 7-8 Charoen Krung Road, Bang Rak, Bang Rak,
