KEYWORD: Rice, Phosphorus deficiency, Spectral reflectance, Genome-wide association

Sompop Pinit : SPECTRAL REFLECTANCE ANALYSIS FOR GENOME-WIDE ASSOCIATION OF THAI RICE *Oryza sativa* L. UNDER PHOSPHORUS-DEFICIENT CONDITION. Advisor: Prof. SUPACHITRA CHADCHAWAN, Ph.D. Co-advisor: Asst. Prof. JUTHAMAS CHAIWANON, Ph.D.

The goals of this research have three main points: (i) to develop a rapid method for inorganic phosphorus quantification, (ii) to investigate spectral reflectance indices representing phosphorus deficiency in rice, and (iii) to determine SNPs associated with phosphorus deficiency tolerance in Thai rice via genome-wide association study (GWAS).

The punching method was developed to enhance the high throughput performance of the conventional Pi extraction and molybdate blue assay. Pi content can be extracted using equally small leaf areas without leaf grinding, balancing, and tedious transferring steps. The punching method provided comparable results to the conventional grinding method with a strong correlation in high and low accumulation rice cultivars under a phosphorus supplement series. Thousands' Pi content of rice samples can be quantified within a few hours, exactly suited for large-scale phenotyping or screening experiments. P deficiency response of 172 Thai rice (*Oryza sativa* L.) accessions grown in three different P concentrations. I detected Pi content and spectral reflectance data by using the punching method and hyperspectral measurement, respectively. Pi content showed sensitive evaluation results to identify P deficient level in each different treatment. For hyperspectral analysis, ratio indices between NIR and VIS wavelength showed a strong correlation with Pi content without spectral interference. The 217 ratio indices and Pi content were associated with 113,114 SNPs derived from the whole-exome sequence. The 48 significant SNPs with low *P-value* were predicted from both R_{750}/R_{700} and R_{740}/R_{560} . At the same time, Pi content association served 15 significant SNPs, which 3 SNPs of these superimposed from the index association. Interestingly, several known genes involving in P deficiency regulation were found that confirmed correct association affected by the performance of the novel phenotypic traits. Overall, the numerous candidate genes exposed their possibility in P deficiency modulation by considering previous gene expression, QTL mapping, and reported function.

ACKNOWLEDGEMENTS

I would like to express my most significant appreciation to my thesis advisor, Professor Dr. Supachitra Chadchawan, who supports my educational chance and is also a perfect role model in work performance and critical thinking. I would like to give my deepest sincere gratitude to my thesis co-advisor, Assistant Professor Dr. Juthamas Chaiwanon, for her kindness, excellent guidance, and suggestions, which will be a good prototype for my scientific career in the future. They are the main factors that improve my ability and stay with me to fight against my research.

I am thankful to the thesis committee, Associate Professor Dr. Sehanat Prasongsuk, Dr. Sarisa Na Pombejra, Associate Professor Dr. Kuakarun Krusong, Dr. Somsong Chotechuen, and Dr. Duangjai Suriya-arunroj for their kindness, excellent guidance, and constructive comment. I wish to acknowledge the help provided by Associate Professor Dr. Teerapong Buaboocha and Dr. Sira Sriswasdi, who suggested and offered many potential data analysis approaches. Moreover, I would like to express my special thanks to Associate Professor Dr. Poonpipope Kasemsap for instrument support and an informative suggestion. I appreciate all the Professors and staff in the Biotechnology program and Department of Botany, Faculty of Science, Chulalongkorn University, for their helpful recommendation and encouragement.

I would like to offer my special thanks to the Royal Golden Jubilee Ph.D. Scholarship Grant (RGJ-Ph.D.) of Thailand Research Fund (TRF) (PHD/0188/2558-2.B.CU/58/AC.1.O.XX) for my doctoral scholarship. This research was financed by the Development and Promotion of Science and Technology Talents Project (DPST) grant fund of the Institute for the Promotion of Teaching Science and Technology (IPST) (024/2558). I would like to thank the Pathum Thani Rice Research Center for the rice seeds used in the study.

My special thanks are extended to the Center of Excellent staff in Environment and Plant Physiology, Department of Botany, Department of Biochemistry, Chulalongkorn University, for their help and fantastic relationship. Finally, my innermost gratitude is expressed to my family, particularly Mr.Somsak Pinit, Mrs.Kingdow Pinit, and Mr.Jun Mark Segundo, and true friends for their sincerity, understanding, and support, which supply me with unlimited willpower to fight against problems and obstacles in my life.

Sompop Pinit

CHAPTER I

INTRODUCTION

Increasing the world's population and expanding the food production industry affect the rising demand for agricultural products to supply their consumption. Rice (*Oryza sativa* L.) is an essential food, because half of the world's population consumes rice as their staple food (Maclean *et al.*, 2013). In Thailand, more than seven million tons of rice has been exported as a major agricultural product in 2019. Nevertheless, productivity has been dropped compared with the previous export year (11 million tons in 2018) (ThaiRiceExportersAssociation, 2020). The decrease in rice productivity might be limited by several factors such as drought, salinity stress, and nutrition deficiency (Batlang *et al.*, 2013). In particular, phosphorus deficiency leads to the disruption of plant growth and development and has become one of the major problems in agricultural products' quality and yields (van de WIEL *et al.*, 2016).

Phosphorus (P) is an essential macro-nutrient for plant growth and development. Lack of P element in plants negatively affects several metabolic processes, including photosynthesis, cellular respiration (Terry and Ulrich, 1973), cellular component synthesis (Li *et al.*, 2016), cellular signaling, and disease resistance (Zhao *et al.*, 2013). Plant adaptation is a response to survive under undesirable conditions. Under P deficiency, plants have developed their metabolic processes to maintain metabolism ability and growth performance, such as root architectural adaptation, uptake adjustment, translocation, utilization efficiency, etc. P-deficiency tolerance is complex adaptation that depends on different morphological, physiological, and biochemical responses in P homeostasis. Therefore, the investigation of genes involving P deficiency response or adaptation is the key to develop tolerance rice cultivars, leading to rice enhancement in tolerance capability. Additionally, the sensitive detection in P deficiency is necessary to identify the

deficient status. The responsible parameters can be applied as phenotypic data in the gene prediction process.

Next generation sequencing (NGS) technology provides high speed and precision of a big genomic dataset, which enables in-depth investigation in genomic function and variation. Genome-wide association study (GWAS) has become an effective method used to dissect the genetic basis of the complex traits by establishing statistical links between phenotypes and genotypes. This procedure, based on single nucleotide polymorphism (SNP) markers, has been extensively applied in rice and other plant species, including sorghum (Shehzad *et al.*, 2009), barley (M. Wang *et al.*, 2012), lettuce (Simko *et al.*, 2009), maize (Li *et al.*, 2013), tomato (Ranc *et al.*, 2012), *Arabidopsis* (Atwell *et al.*, 2010), soybean (Contreras-Soto *et al.*, 2017) and bread wheat (Zanke *et al.*, 2014), to identify causative genes involved in agronomic traits and stress responses. GWAS accuracy to predict the high potential causative loci relies on good phenotypic traits (MacRae and Vasan, 2011). Some biochemical parameters are sensitive and direct measurement for plant responses to stress. However, the phenotyping procedures are often time-consuming and labor-intensive, which are not suitable for large scale phenotyping for GWAS (W. Yang *et al.*, 2014).

Inorganic phosphorus (Pi) content is a sensitive parameter for plant P status, which indicates the internal availability of Pi level in the plant. It can determine the ability of plant adaptation under the P-deficient state. However, a conventional protocol of Pi quantification in plant tissue includes numerous and tedious steps, such as grinding, balancing, and centrifuging, which are time-consuming, and labor-intensive that are inappropriate for high throughput measurement, required for GWAS application (Mori and Nakamura, 1959; Turner and Turner, 1961; Kanno *et al.*, 2016). For quantifying Pi content of thousands of samples for the GWAS application, development of the quantifying method is necessary to improve and establish a faster and easier quantification protocol to handle the large-scale quantification.

Hyperspectral detection, which is fast and non-destructive, has been developed and applied to detect plant response in various stresses. A high-performance sensor has been created to observe photo-reflectance from the plants based on light's physical property. Phenotypes can be indirectly observed from spectral reflectance, which is intensity of each wavelength spectrum reflected by plant tissues. Differences in spectral reflectance can indicate plant status and used as an alternative parameter in several applications (Kokaly *et al.*, 2009). Over the past years, many indices of spectral reflectance are reported to indirectly represent several plant phenotypes, including leaf greenness (Zarco-Tejada *et al.*, 2005), yield quality (Kanning *et al.*, 2018), water stress (Jones *et al.*, 2004), protein (D. Sun *et al.*, 2019), chlorophyll (Yang *et al.*, 2015), carotenoid (Yang *et al.*, 2010), and anthocyanin content (Gu *et al.*, 2018). Thus, hyperspectral indices could be another effective trait that can provide an easy and convenient investigation process for the GWAS application.

Objectives of this study

1. To develop a rapid method for inorganic phosphorus quantification
2. To investigate spectral reflectance indices responsive to phosphorus deficiency in rice
3. To determine SNPs associated with phosphorus deficiency tolerance in Thai rice *via* genome-wide association study (GWAS)

CHAPTER II

LITERATURE REVIEW

1. Rice - the essential agronomical crop

1.1 The global rice productivity

Rice (*Oryza sativa* L.) is one of the world's valuable staple food crops and indispensable for more than half of the globe's population, particularly in Asian countries. Besides, rice is an important food source, which abundantly provides more calories for people's diets than maize, wheat, potato, or cassava (Maclean *et al.*, 2013). In 2019, a total of 495.9 million tons of rice was supplied for world wild consumption. Almost all (90%) rice production is in Asian countries, including China, Vietnam, Philippines, Indonesia, Myanmar, Japan, India, Bangladesh, Cambodia, and Thailand. Thailand was the world's second-biggest exporter after India in the same year (Workman, 2020), which exported 7.58 million tons (130.6 billion baht) (ThaiRiceExportersAssociation, 2020). However, rice productivity has been decreased by several factors when compared with the previous year's export (**Figure 1**).

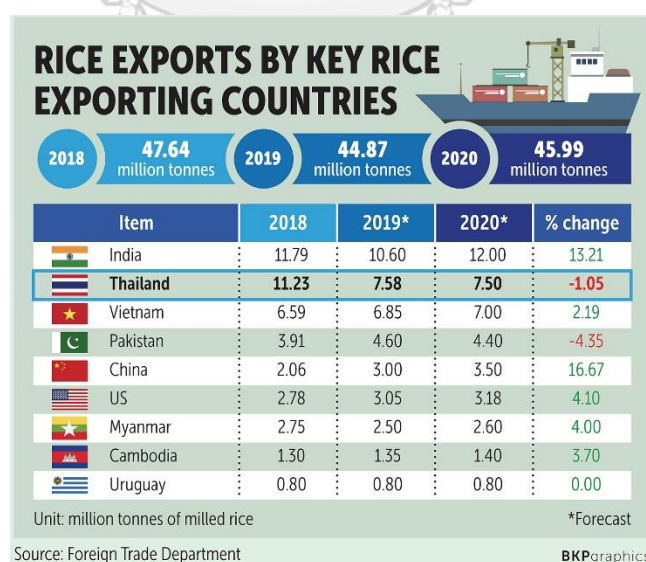

Figure 1 World's top 9 rice exporters (in million tonnes) over three years (2018-2020) and their percentage of relative export changing.

1.2 Genetic variation of rice

A couple of rice species are the most popular and essential cereals for human diets, including *O. sativa* (worldwide grown) and *O. glaberrima* (grown in West Africa). The rice genus (*Oryza*) comprises 27 species, 11 genome classification, and four relation series (**Table 1**). Each rice species contributes to its specific location around the world. The genome variation of each species was evolved and diversified from the origin since 14 million years ago in Malesia. The labeled AA to LL was applied to classified genome variation among rice species. The number of letters was used to indicate genome copy numbers (diploid or tetraploid) described in **Table 1**. In the ecological diversification of *O. sativa*, the two major variety groups were isolated as indica and japonica. The rices that adapted to grow in the tropical areas, were named indica group, and the others that adapted for the temperate zone, and tropical uplands were named japonica group. Nowadays, an in-depth molecular investigation classified three other divergent groups (**Figure 2**). The japonica was sub-diversified as temperate and tropical japonica. Besides, aus group was a divergent sub-species from the indica group cultivated in India and Bangladesh (Maclean *et al.*, 2013).

In Thailand, thousands of rice cultivars have been developed by natural selection, human selection, and breeding for over 5000 years (Techarang *et al.*, 2019). From a high variation of Thai rice, the rice population can be sub-classified using ecological growing, light period sensitivity, or amylose content. Moreover, some rice cultivars have a specific character derived from evolution processes, such as purple rice (e.g. Riceberry), fragrant rice 'KDML105', floating rice (Pin Kaew 56), etc. Consequently, Thai rice varieties contain high genetic variation that has provided a treasure of genetic materials for genetic investigation and breeding improvement (Vanavichit *et al.*, 2018). Previous reports showed a potential genetic variation of Thai rice in genetic structure, salt tolerance, and root anatomical structure (Chakhonkaen *et al.*, 2012; Vejchasarn *et al.*, 2016; Chokwiwatkul *et al.*, 2017).

Figure 2 Population structure and relatedness of *O. sativa* over 234 accessions which characterized by the genetic investigation based on nuclear SSR and chloroplast markers (Kovach *et al.*, 2007).

1.3 Stress affects rice productivity

Nowadays, rice production is dramatically reduced by several factors that affect rice growth and development. The high temperature (LÜ *et al.*, 2013), drought (Mukamuhirwa *et al.*, 2019), salinity (Zeng *et al.*, 2003), and nutrient-deficient stress directly caused by poor soil quality (Fageria, 2001) have been reported as factors that affect rice production by inhibition of rice growth. Poor soil quality was found throughout Thailand's area (**Figure 5A**). Lack of macronutrients (nitrogen, phosphorus, and potassium) in soil negatively results in growth and limits crop productivity (Liu *et al.*, 2011; Sadiq *et al.*, 2017; Lozano Fernández *et al.*, 2018). For improving and raising rice production, the demand for N, P, and K fertilizer is dramatically increased every year (FAO, 2017) (**Table 2**). Among the macronutrients, potassium is the least of the problems due to its high concentration in soil (up to 20,000 ppm) (Halperin and Kamel, 1998). For N fertilizer, atmospheric nitrogen can be fixed by the Haber-Bosch process or biological nitrogen fixation by microorganisms. Thus, the N fertilizer is unlimited to sustain the world's demand (Basosi *et al.*, 2014). P fertilizer is only derived from non-renewable phosphate rock, which needs at least 300 years in mineral regeneration by the natural process (Samreen and Kausar, 2019). The over-application of P fertilizer in agriculture not only leads to increasing unavailable P forms in the soil, but also dramatically affects the declination of phosphate rock resources in nature.

Table 2 World's trending demand of N, P, and K fertilizers during 2015-2020 (thousand tonnes) (FAO, 2017).

Year	2015	2016	2017	2018	2019	2020
Nitrogen (N)	110,027	111,575	113,607	115,376	117,116	118,763
Phosphate (P ₂ O ₅)	41,151	41,945	43,195	44,120	45,013	45,858
Potash (K ₂ O)	32,838	33,149	34,048	34,894	35,978	37,042
Total (N+P ₂ O ₅ +K ₂ O)	184,017	186,668	190,850	194,390	198,107	201,663

2. Phosphorus deficiency

2.1 Phosphorus - the indispensable plant nutrient

Phosphorus (P) is a necessary and indispensable macronutrient, which is vital for plant metabolism, involving membrane synthesis, energy transfer, enzyme activation, nucleic acid generation, nitrogen fixation, and carbon metabolism (Schachtman *et al.*, 1998). P starvation inhibits plant growth and development (Vance *et al.*, 2003). P deficiency has occurred from two major reasons involving the soil property. Firstly, a shortage of P deficiency happened due to insufficient P addition to the farming system. The deficiency can be easily solved by supplementing P fertilizer input. Secondly, the unavailable form of P causes deficiency by which P is fixed with soil particle or some other elements as a complex. Previous studies reported that high pH could induce P complex with iron (Fe) or aluminum (Al), and low pH could also stimulate precipitation with calcium (Ca). Moreover, overapplication of P fertilizer indirectly leads to a higher rate of unavailable P formation in the soil by increasing soil pH (Haefele *et al.*, 2014).

2.2 Plant response and adaptation to phosphorus deficiency

Rice has developed the complicated mechanism and adaptation to maintain their homeostasis under P deficient condition. The adaptation can be classified into two categories, including P utilization efficiency and P acquisition efficiency (Aziz *et al.*, 2014). The P utilization efficiency is the ability to efficiently use limited P and adjust the internal process to maintain P homeostasis. The internal P remobilization, metabolism modification, membrane reorganization, and growth enhancement with limited P are examples of P use efficiency adaptation. In contrast, P acquisition efficiency adaptation mainly focuses on external P foraging *via* root system architecture adaptation, phosphatase exudation releasing, and P uptake enhancement.

In detail, P remobilization tries to translocate stored P from older to younger tissues for maintaining metabolism in young organs (Gill and Ahmad, 2003). Interestingly, the plant can modify an alternative pathway across the P-involving

steps that helps the plant drive the metabolism, such as the alternative pathway of cytosolic glycolysis and electron transport (Plaxton and Carswell, 1999; González-Meler *et al.*, 2001). Sulfo- or galactolipid can be alternatively used instead of phospholipid molecules for membrane components (Pant *et al.*, 2015). For root system architecture, three major adjustments are modulated under P starvation, including root elongation to forage new resources of available P, lateral root formation to enhance exploration, and root hair development to increase root surface area (López-Bucio *et al.*, 2002) (**Figure 3**). For transforming unavailable P, root exudates (acid phosphatases or phytases) are excreted from roots to convert P into available P forms (Neumann and Römheld, 1999). Plants had evolved low and high-affinity transporters to increase P acquisition and internal distribution under P starvation (Liu *et al.*, 1998). Moreover, root symbiosis with arbuscular mycorrhiza provides extending surface area and increases uptake ability. Symbiotic interaction is dramatically induced under P starvation by exuding plant-fungi interaction hormone (Bedini *et al.*, 2018). In addition, P deficiency inhibits elongation of the lamina joint by decreasing brassinosteroid biosynthesis that changes leaf angle as an upright leaf phenotype. This phenomenon helps plant to reduce light receiving and photosynthesis under P indigent situation (Ruan *et al.*, 2018).

Figure 3 Leaf angle and root system architecture adaptation in rice under phosphorus deficiency (A-F). P deficiency decreased leaf angle (A) by inhibition of lamina joint (B). 3D illustration of different inhibition in both lamina joint sides. P starvation increases root elongation (D-E) and root hair density (F) (Zhou *et al.*, 2008; Ruan *et al.*, 2018).

2.3 Phosphorus responsive and tolerance genes in rice

The adaptation and response to P deprivation are modulated by network regulation of cascade genes. *OsPHR1* and *OsPHR2*, homologous transcription factor genes, are center regulators in P starvation signaling pathway. They directly bind to P1BS cis-element in the promoters of phosphate starvation-induced (PSI) genes to regulate their expression (Zhou *et al.*, 2015). Moreover, *OsPHR2* is negatively controlled by *OsSPX* encoding protein in a Pi-dependent manner, which acts as a Pi detective sensor in plant cells (Wang *et al.*, 2014). Under P deficient condition, expression of PSI genes, including *OsIPS1/2*, *Os-miR399*, *OsPTs*, *OsPAPs*, and *OsSQD2*, are triggered to modulate plant adaptation in both P utilization efficiency and P acquisition efficiency. High expression of *OsPTs*, phosphorus transporter genes, controls higher Pi uptake and remobilization into the essential organs. Similarly, *OsPAPs* and *OsSQD2* promote Pi recycling from membrane phospholipids and releasing of acid phosphatase to breakdown fixed P. *Os-miR399* functions to control the expression level of *OsPHO2*, which negatively regulates other PSI genes. *OsIPS1/2*, which are non-coding genes, act by sequestering miR399 from degrading PHO2 (Franco-Zorrilla *et al.*, 2007).

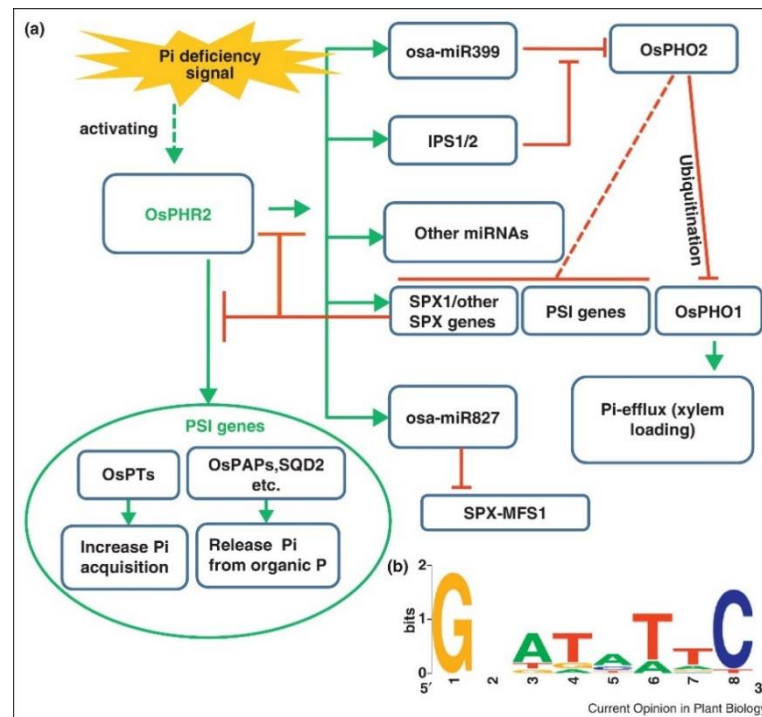

Figure 4 Phosphorus deficiency signaling involved in P deficiency adaptation and response (Wu *et al.*, 2013).

P deficiency signaling pathway is shown in Figure 4. Overexpression of some regulatory genes result in increased adaptation and tolerant efficiency under P starvation, such as *OsPHR2*, *OsPAP10*, *OsPT6*, etc. Rice overexpressing *OsPHR2* resulted in the increase of P adaptation by enhanced root elongation, root hair proliferation, Pi transporters, and Pi accumulation (Zhou *et al.*, 2008). In P-fixing soil, *OsPAP10c* overexpressing rice exhibited acid phosphatase activity to breakdown fixed P and then turned it to usable forms. Higher Pi accumulation was found and caused by high root acquisitional performance (Lu *et al.*, 2016). Transgenic rice overexpressing a high-affinity Pi transporter *OsPT6* could store high P content in their leaves and promote greater yield productivity with more numerous tillering under P starvation (Zhang *et al.*, 2014). One well-known P deficiency tolerance gene, *OsPSTOL1*, was identified from tolerance rice cultivars grown under P deficient soil by QTL technique. Pup1 QTL was identified from 30 rice accessions, including aus rice

variety in the population (**Figure 5a**). In comparison with the Nipponbare genome sequence, 120 kbp of the Pup1 region of Kasalath rice was absent from the Nipponbare genome (**Figure 5b**). The deletion of *OsPSTOL1* in the Pup1 region causes more susceptibility to P deficiency in Nipponbare (Heuer *et al.*, 2009). Transformation of *OsPSTOL1* into IR64 rice, which is a PSTOL1-absent genotype, could boost tolerance adaptation from P sensitive IR64 rice in both P sufficient and deficient conditions. Improved yield production, P uptake, and root surface area confirmed tolerance enhancing function of the *OsPSTOL1* gene (Gamuyao *et al.*, 2012).

Figure 5 Soil problem in Asia and distribution of aus-type rice (a). The relative position of Pup1 genes between the Kasalath and Nipponbare rice genome (b) (Gamuyao *et al.*, 2012).

3. Phosphorus quantification

3.1 Conventional phosphorus quantification methods

To study phosphorus deficiency and their adaptation in plants, phosphorus determination to understand P concentration changes is essential. Phosphorus quantification techniques are sensitive measurements, particularly in plant tissues. Several quantifying processes have been established for different strengths and weak points, such as colorimetric assay, X-ray spectrometry, inductively coupled plasma (ICP), nuclear magnetic resonance (NMR), etc. But the colorimetric assay is still popular due to its cheap rate and unnecessary complex detecting machine. Recently, molybdenum blue and malachite green are two useful colorimetric assays using for P quantification. The molybdenum blue reaction is more common in the application due to wider range of detection in P concentration than the malachite green approach. Molybdenum blue reaction is used to determine orthophosphate (PO_4^{3-}) molecules, inorganic form of phosphorus in nature, which finally forms blue-colored product. In detail, the reaction includes two major steps that a single orthophosphate (hetero-atom) firstly combines with a dozen molybdate molecule (addenda-atom), and then forms Keggin structure (**Figure 6**). Secondly, the complex structure is continuously reduced to molybdenum blue species (blue colored molecule) by the reductant, ascorbic acid, as shown in equation (1) and (2) (McKelvie *et al.*, 1995).

Figure 6 The Keggin structure of phosphomolybdate generating from the combinational reaction of P-hetero atom and molybdenum-addenda atom (Klemperer, 2007).

3.2 Limitations of the conventional quantification methods

By the molybdate blue reaction, the measurement step is not the time-limiting factor of Pi quantification in plants. However, the extraction step, which releases Pi molecule from plant tissues, is precisely the problem from the tedious steps, time consumption, and low throughput. From method consideration, three main issues in the extraction involve sample balancing, numerous times-pipetting, and grinding.

The initial sample's weight is essential and generally used for several quantifications to estimate accurate concentration and interpretation by normalizing the initial sample unit. However, balancing small fresh tissue is inconvenient and error-prone, which needs very sensitive and expensive balance. Besides, working with uncontrollable time and environment affects weight loss from water evaporation in the tissue that influences accurate weight. Alternatively, area normalization had been used to quantification of chlorophyll content (Hamblin *et al.*, 2014; Liang *et al.*, 2017) and root Pi content (Ayadi *et al.*, 2015).

Several times of pipetting, including chemical addition and supernatant transferring, in several repeated step are tedious work and time consuming. The modified method using a microplate reader and multichannel pipette is an alternative way to standardize and encourage high-throughput measurement (Auld *et*

al., 2020). Nowadays, many improved high-throughput methods have developed by performing with microplate and multichannel pipette to enhance the platform speed and easy to perform (Salvo-Chirnside *et al.*, 2011; Hawkins and Storey, 2017; Gilbert-Girard *et al.*, 2020; Koepke *et al.*, 2020). Besides, the fixed location of the microplate provides less labeling in each sample, that I can map the sample description with location of wells in the plate *via* computational mapping (Auld *et al.*, 2020).

Hard-working and loss of uncountable equipment are sacrificed for tissue grounding to release intracellular Pi content. Freeze shattering process provides a single step to permeabilize plant cell walls, containing the excess intracellular substance to the extraction solution by freezing tissue at deep frozen condition (Wasteneys *et al.*, 1997). This technique has previously been demonstrated in plant protoplasts (Tiwari and Polito, 1990), algae cells (Braun, 1996), and various plant materials (Wasteneys *et al.*, 1997).

4. Hyperspectral sensing - a non-destructive detection approach

4.1 Principle and development

Hyperspectral detection is a new and accessible technique to identify plant response against stresses and diseases, subtle symptoms, with non-destructive property (Kokaly *et al.*, 2009). The hyperspectral detection device provides high-fidelity reflectance information over the light spectrum, including visible (VIS) and invisible wavelengths (**Figure 7**). In the analysis, the large and complicated spectral information can distinguish various responses in plants. The spectrum can be considered from about 250 nm (ultraviolet; UV) to 2,500 nm (short wave infrared; SWIR), which includes a subset of different spectrum type, including UV (250-400 nm), VIS (400-700 nm), NIR (700-1,300 nm), and SWIR (1,300-2,500 nm) (Pandey *et al.*, 2017). Thus, performance of a spectrometry depends on the range coverage and frequency of detective sensor. For plants, the highly potential information is in

the VIS and NIR wavelength regions (**Figure 8**). VIS is mainly affected by absorbance of pigments, such as chlorophyll, carotenoid, xanthophyll, anthocyanin. In contrast, NIR informs in turgid of plant cell structure, which usually has high reflectance in a healthy plant. Additionally, SWIR indicates leaf water content and lignocellulose (Peñuelas and Filella, 1998). One interesting part is at the red edge position (690-740), in which the reflectance suddenly increases. This change is a specific response to photosynthetic pigments. The reflectance at wavelength up to ~ 700 nm is low due to dramatical absorption of photosynthetic pigments. After ~ 720 nm, the reflectance suddenly rises over the red edge region and is then quite steady with high reflectance at the NIR zone (Cho and Skidmore, 2006). Several indices were developed from these interesting spectra, such as NDVI, RECI, TNDVI, MCARI, IRECI, and PSSR. (Psomiadis *et al.*, 2017).

Figure 7 Different types of the electromagnetic spectrum along with wavelength range. The diagram displays visible and infra-red regions (Lowe *et al.*, 2017).

To address plant responses to different conditions, representative wavelengths, which are highly altered under the different conditions, is considered important in the spectrum. The combination of two or more representative wavelengths in the spectrum is used to generate specific vegetative indices. Nowadays, many indices have been investigated to represent plant status and

response indirectly. For example, normalized difference vegetation index (NDVI) was established by NASA scientists to analyze Earth's relative greenness using satellite tele-observation (Rouse Jr *et al.*, 1974). The index was calculated by a simple ratio of the NIR and VIS spectrum. NDVI information helps in environment management by tracking plant vegetation structure, such as agricultural interference, droughts or forest declination (Borowik *et al.*, 2013). Plant pigment indices have been developed to estimate the content of chlorophylls, carotenoids, and anthocyanin. Chlorophyll absorption reflectance index (CARI) (Kim, 1994), modified CARI (MCARI) (Daughtry *et al.*, 2000), and chlorophyll red-edge index (Clred edge) (Gitelson *et al.*, 2006) have been created to improve the accuracy and effectiveness. Different forms of carotenoids, such as violaxanthin and zeaxanthin, can be identified by its individual detective index (CRI1 and CRI2, respectively) (Gitelson *et al.*, 2002). Anthocyanin content indices (ACI) were derived from dividing between green and red reflectance, and the ACI was then modified by normalizing with NIR reflectance (Gamon and Surfus, 1999). Moreover, water deprivation can be determined with the NDII index, which contributed to NIR and SWIR reflectance (Hunt Jr and Rock, 1989). Furthermore, some indices provide multiple purposes, such as NDWI, WBI, SIPI, RGRI, and MSI (**Table 3**) (Roberts *et al.*, 2016).

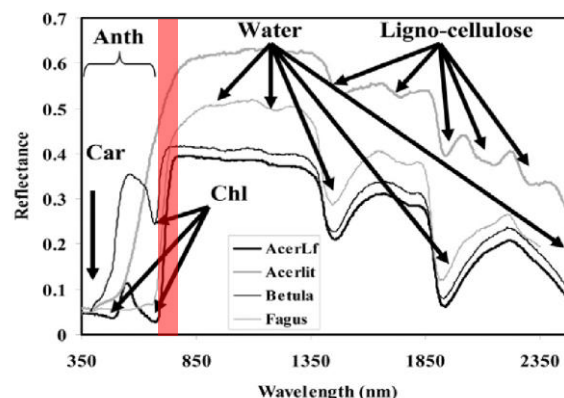

Figure 8 Illustration of reflectance along the spectral wavelength of different samples growing in various locations. The red edge section was highlighted in red (690–740 nm) (Roberts *et al.*, 2016).

Table 3 Summary of some hyperspectral Indices, relevant formulas, and description. Highlight in grey are indices using for multiple purposes (Roberts *et al.*, 2016).

4.2 Hyperspectral application in plant stress response

Hyperspectral observation has been applied for many plant stresses, such as drought, salt stress, plant disease, and nutrient deficiency. Moreover, different plant species also show different response phenotypes, which can be detected by different hyperspectral indices. Jones *et al.* (2004) applied hyperspectral analysis to investigate the effect of water stress in three plant species, including corn, spinach, and snap bean, *via* monitoring of conventional plant water content, spectral bands, and spectral indices. The spectral band at 1,450 nm derived from corn and snap bean resulted in a high correlation with plant water content, while the spinach was the band at 950-970 nm. Reflectance detection at 300-2,550 nm region of corn leaves grown in various irrigation rates showed three representative regions along the spectra (VIS, NIR, and SWIR), which illustrated different responsive spectra between the treatments. Thus, the indices based on ratio across spectral regions could exhibit higher sensitivity in drought stress detection (El-Hendawy *et al.*, 2017). In salinity stress, Moghimi *et al.* (2018) used the hyperspectral imaging pipeline to identify salt stress tolerance in wheat, which offered simple processing and data analysis by associating a machine learning platform. Machine learning helped to investigate complex and high dimensional interaction within hyperspectral information. A similar approach was studied in okra (*Abelmoschus esculentus* L.) under salt stress condition that machine learning-based reflectance analysis provided high-efficiency prediction to calculate the predicted value of SPAD, sodium content, photosynthetic rate, and transpiration rate without traditional phenotyping procedures (Feng *et al.*, 2020). In a complex phenotype as plant disease caused by virulent fungi, charcoal rot disease in soybean could be identified by a novel 3D deep convolutional neural network (3D-DCNN). Based on hyperspectral image acquisition, the 3D-DCNN offered 95.73% accuracy in disease classification by intelligent classification model, which was assessed from the sensitive reflectance information at the NIR region (Nagasubramanian *et al.*, 2019).

Under nutrient deficiency, three major macronutrients (N, P, and K) were mainly focused and attempted to develop the non-destructive measurement processes. Peng *et al.* (2020) applied hyperspectral technology and generated potential indices for degraded vegetation. Three macronutrients in six species were *in situ* performed hyperspectral data collection and nutrient quantification. The exact estimation indices were established from 43 responsive indices, optimized *via* linear regression analysis. These useful indices can be used for airborne and satellite hyperspectral information. For forest observation, hyperspectral tele-capturing or available Google Earth Engine dataset can be analyzed and detected nutrient deficiency area by analyzing a responsive reflectance spectrum (Walshe *et al.*, 2020). For more convenient and accurate use of hyperspectral imaging, in field hyperspectral camera (Hypspec push-broom) was built and automatically used for N content estimation of sugar beet leaves (**Figure 9**). Predicted N content showed sufficient correlation ($r^2=0.86$) with actual N content that can be applied to study N content distribution along with leaf samples (Jay *et al.*, 2014). For sensitive detection of P and K in tea leaves, modified NIR based spectral indices were established by pre-processing model improvement to eliminate noise interference of raw spectral data. The developed model could predict high coefficient indices ($r^2=0.94$ and 0.92) for P and K content in tea leaves, respectively (Wang *et al.*, 2020).

Figure 9 Phenotyping platform with the hyperspectral camera for N content detection (Wang *et al.*, 2020).

5. Genome-wide association study

5.1 Key concept

Since next-generation sequencing technology had been established, the powerful investigating tool called genome-wide association study (GWAS) was also emerged to identify causative genetic positions on the genome in several phenotypes and species of interest. GWAS is the successful method used to dissect the genetic basis of the complex traits by establishing statistical links between phenotypes and genotypes (**Figure 10**). Based on four different nitrogenous bases (A, C, T, and G) inscribed within billions of DNA molecules of genome sequences, an individual nitrogenous base altering in the same position among the study population is one of potential variations (**Figure 11**), which called single nucleotide polymorphism (SNP). SNP potentially causes a mutation in an organism that informs the genome history over the past. The non-random interaction of SNPs is the historical evidence representing the mutation or recombination rate of genome passing through the generation, which is called linkage disequilibrium (LD). The different types of variable SNPs can be used to represent the genotype of the population in GWAS analysis. To reduce false positives, the genotypic data are typically pre-processed by performing a quality control process to filter low potential variation before the association step.

Figure 10 A diagram view of sequencing-based genome-wide association process in rice (Han and Huang, 2013).

Another essential requirement for GWAS is responsive traits of the interesting phenotype, which enables the quantitative or case-control value. Quantitative data are more informative than case-control data in the association by its more dimension of data. For association analysis, each individual SNP is statistically associated and tested the null hypothesis with the phenotypic data. The linear regression model, called the general linear mix model, is typically used for quantitative parameters. Association software, which provides the general linear mix model, includes GEMMA (Zhou and Stephens, 2012) and EMMA (Kang *et al.*, 2008). Moreover, several novel association platforms have been developed to improve the association efficiency, such as the integration of Kruskal–Wallis test with empirical Bayes (pkWemEB) (Ren *et al.*, 2018), easyGWAS (Grimm *et al.*, 2012), GWASpro (Kim *et al.*, 2019), GWAS Atlas (Tian *et al.*, 2020).

Figure 11 Illustration of four SNPs comparison of three independent genomes.

5.2 Application of genome-wide association study in rice

Since the GWAS launched for research in gene identification, numerous plant species, such as sorghum (Shehzad *et al.*, 2009), barley (M. Wang *et al.*, 2012), lettuce (Simko *et al.*, 2009), maize (Li *et al.*, 2013), tomato (Ranc *et al.*, 2012), *Arabidopsis* (Atwell *et al.*, 2010), soybean (Contreras-Soto *et al.*, 2017), bread wheat (Zanke *et al.*, 2014), pepper (Colonna *et al.*, 2019), and particular rice (Huang *et al.*, 2012; Wu *et al.*, 2015), have been applied with various agronomic parameters under control or stress conditions. Rice is a suitable plant model use for genetic investigation for several reasons. It has a small size of the genome, short-life cycle, diploid alleles, and self-fertilization. Moreover, the complete and informative reference genome databases were already established and available in both indica and japonica varieties (Yu *et al.*, 2002; Kawahara *et al.*, 2013).

For the P deficiency response gene, Wissuwa *et al.* (2015) used the internal P utilization efficiency (PUE) trait derived from 413 rice accessions under comparative P starvation. The significant loci were identified from the association on chromosome 1, 4, 11, and 12, which included 14 candidate genes. Gene expression analysis from rice grown under P starvation showed the high response of the candidate genes.

A responsive gene encodes a nucleic acid-binding protein (LOC_Os01g13090) with an RNA ligase/cyclic nucleotide phosphodiesterase, which was found to be highly expressed in old leaf tissue. Interestingly, GWA of SNPs derived from a comparison between low P tolerant and sensitive rice identified several SNPs located in P responsive and root system architecture genes (Poonam Mehra *et al.*, 2015).

In the case of hyperspectral detection in rice, red edge (680-760 nm) derived indices showed a high correlation with chlorophyll content. GWA association of the indices could identify chlorophyll regulated genes as well as chlorophyll-related traits (Feng *et al.*, 2017). Furthermore, hyperspectral imaging has been used to determine grain quality in rice seeds. The impact ratio spectrum of VIS and NIR regions (702-900 nm) was used as representative indices and associated with the SNP genotypes. The result indicated several grain-quality related genes that could confirm hyperspectral qualification capacity (Barnaby *et al.*, 2020). Similarly, D. Sun *et al.* (2019) could use the hyperspectral NDSI index instead of protein content due to their high correlation efficiency. GWA of both NDSI and protein content identified the same candidate genes. The hyperspectral trait measurement has a potential to apply for GWAS investigation of P deficiency.

CHAPTER III

MATERIALS AND METHODS

1. Materials

1.1 Plant materials

Seeds of 172 Thai rice (*Oryza sativa* L.) accessions, including Thai rice varieties and breeding cultivars used in this study, were obtained from National Rice Seed Storage Laboratory for Genetic Resources, Pathum Thani Rice Research Center, Rice Department, Ministry of Agriculture and Cooperatives (Table 4).

1.2 Equipments

- -20°C deep freezer (Mitsubishi electric, Japan)
- -80°C deep freezer (Thermo-Scientific, USA)
- 3-mm diameter paper puncher
- 4°C refrigerator (Hitachi, Japan)
- 40-liter plastic boxes
- 80-liter foam boxes
- 100-liter plastic tank
- Hot air oven (Binder, USA)
- Ice foam box
- Micropipette (Mettler Toledo Rainin, USA)
- Microplate reader (Molecular Devices, USA)
- Mortar and pestil
- Multichannel micropipette (Mettler Toledo Rainin, USA)
- pH meter (Mettler Toledo, USA)
- Pipetting filler (Mettler Toledo Rainin, USA)
- Plastic net

- PolyPen RP 400 (UV-VIS) (Photon Systems Instruments, Czech Republic)
- Portable pH meter
- PVC pipe
- Refrigerated centrifuge (Hettich Zentrifugen, Germany)
- Reverse osmosis water filter (Colandas, USA)
- Seed Starter Tray
- Vortex shaker (Scientific Industries, Inc., USA)

1.3 Chemical and reagents

All chemical and reagents used in this study were analytical grade and produced by different companies as described below.

- Ammonium molybdate tetrahydrate; $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}$ (Alfa Aesar, United Kingdom)
- Ammonium nitrate; NH_4NO_3 (Ajax Finechem, Australia)
- Ascorbic acid; $\text{C}_6\text{H}_8\text{O}_6$ (Acros Organics, Belgium)
- Boric acid; H_3BO_3 (Merck, Germany)
- Calcium chloride hexahydrate; $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ (Ajax Finechem, Australia)
- Commercial bleach (Clorox, USA)
- Copper sulfate pentahydrate; $\text{CuSO}_4\cdot 5\text{H}_2\text{O}$ (M&B, England)
- Dipotassium phosphate; K_2HPO_4 (Ajax Finechem, Australia)
- Ferric sodium EDTA; FeNaEDTA (Himedia, India)
- Hydrochloric acid; HCl (Merck, Germany)
- Magnesium sulfate heptahydrate; $\text{MgSO}_4\cdot 7\text{H}_2\text{O}$ (Daejung, Korea)
- Manganese chloride tetrahydrate; $\text{MnCl}_2\cdot 4\text{H}_2\text{O}$ (M&B, England)
- Molybdate blue reagent (see in Appendix B)
- Perchloric acid; HClO_4 (Loba Chemie, India)
- Potassium sulfate; K_2SO_4 (Daejung, Korea)

- Potassium dihydrogen phosphate; KH_2PO_4 (Daejung, Korea)
- Sodium chloride; NaCl (J.T.Baker, Malaysia)
- Sodium hydroxide; NaOH (Daejung, Korea)
- Yoshida solution (see in Appendix A)
- Zinc sulfate heptahydrate; $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ (Ajax Finechem, Australia)

1.4 Consumables and supplies

- 1.5 ml microtube (Extragene, USA)
- 15 ml plastic tube (Nest Scientific, USA)
- 50 ml plastic tube (Nest Scientific, USA)
- 96-deep well plates (Greiner Bio-One, Austria)
- 96-well plates (Greiner Bio-One, Austria)
- Aluminum foil
- Dry ice
- Glossy paper
- Hydroponic sponge
- Ice
- PP Plastic bag
- Liquid N_2 (TIG, Thailand)
- Multiple channel pipette tips (Mettler Toledo Rainin, USA)
- Pipette tips (Nest Scientific, USA)
- Tissue paper
- Transparent sticker

2. Methods

2.1 Development of rapid inorganic phosphorus quantification

2.1.1 Plant cultivation

Thai rice (*Oryza sativa* L.), including LEUANG CHUMPAE (high Pi accumulator) and NAH KWAN (low Pi accumulator) (**Table B2**), were used to evaluate the method for inorganic phosphorus quantification. Seeds were surface sterilized with 30% commercial bleach (Clorox, containing 6% sodium hypochlorite) for ten minutes and then washed with distilled water three times. Next, the seeds were soaked in distilled water for two days to initiate seed germination. The initiated seeds were continuously floated on a plastic net in half-strength Yoshida solution (Yoshida et al., 1976) for six days. Then, the seed endosperm was cut from the seedlings to remove the phosphorus storage resource, and then the seedlings were transferred to a full-strength Yoshida solution containing different P concentrations, 320, 160, 80, 16, and 0.8 μM NaH_2PO_4 , for 16 days. An equal concentration of NaCl was applied to compensate for the decrease of NaH_2PO_4 in the treatments. The nutrient solution was renewed every four days and adjusted pH at 5.8 daily. The experiments were performed in a greenhouse with the natural environment (30-38°C day/26-30°C night temperature; 40-70 % day/70-90% night humidity; 11 h photoperiod of natural light (400-1,900 $\mu\text{mol m}^{-2} \text{s}^{-1}$) using completely randomized design (CRD) with 24 replications.

2.1.2 Conventional extraction method

Leaf tissue was weighed to about 50 mg and grounded using liquid nitrogen. The powder was mixed with 100 μl of 10% (w/v) perchloric acid. Then the homogenate was diluted ten times with 5% (w/v) perchloric acid and incubated on ice for 30 min. The sample was centrifuged at 10,000x g for 10 min at 4 °C (Nanamori et al., 2004). The supernatant was collected and used for the next Pi measurement step.

2.1.3 Pi measurement

The supernatant was added with 160 μl Molybdate Blue reagent, which contained 0.4% (w/v) ammonium molybdate in 0.5 M H_2SO_4 (A solution) with 10% ascorbic acid (B Solution) (A: B = 6:1) and then incubated at 40 °C for 20 min. The absorbance was detected at 820 nm wavelength *via* microplate reader. The Pi content was analyzed by comparing with the standard curve (**Figure D1**) and calculated as nmol per leaf disc area (mm^2) or μmol per gram fresh weight.

2.1.4 Method development

2.1.4.1 Optimization of incubation time

Twenty leaf discs collected from the seedlings grown under 320 or 16 μM NaH_2PO_4 treatment of high and low Pi accumulator, respectively, were separated into five groups (four discs per group) and kept at -80 °C until use. One group was used for the conventional extraction method. The others were used for incubation time optimization. Four discs were put in a 96-well plate, and then, 200 μl of 5.5 % (w/v) perchloric acid was added to each well and incubated on ice for 1, 2, 3, or 4 hours. Then, supernatants were transferred into a new 96-well plate and diluted with 5.5 % (w/v) perchloric acid up to 80 μl of the final volume. The diluted supernatants were used for Pi measurement according to the method in 2.1.3. Suitable incubation time was applied to quantify Pi for the next step. The experiment was performed with ten biological replicates.

2.1.4.2 Validation of the punching quantification method

The validation of the method was performed using the leaf tissues from seedlings of the high (LEUANG CHUMPAE) and low Pi accumulator (NAH KHWAN), grown in the nutrient solution supplemented with different levels of NaH_2PO_4 (320, 160, 80, 16, and 0.8 μM), which resulted in varying levels of Pi contents. For measurement, second fully expanded leaves of 24 day-old seedlings were folded in half twice, put over glossy paper, and punched together to cut the leaves into equal size using paper puncher (3 mm diameter) and put the discs into a 96-well plate.

Four-leaf discs were collected for the newly developed method (punching method), and the residual leaf section was collected for the conventional measurement method, as described in 2.1.2. The tissues were stored at $-80\text{ }^{\circ}\text{C}$. Then, the 96-well plate containing four leaf discs in each well was added with $200\text{ }\mu\text{l}$ of 5.5% (w/v) perchloric acid and incubated on ice with the appropriate period time as identified in 2.1.4.1. The supernatants were transferred into a new 96-well plate using a multichannel pipette and diluted with 5.5% (w/v) perchloric acid up to $80\text{ }\mu\text{l}$ of the final volume (**Figure 12**). The diluted supernatants were used for Pi measurement in 2.1.3. Pi concentration derived from the conventional extraction method and the punching method were calculated. Pearson's correlation was performed to validate Pi content measured by the punching and conventional methods. The experiment was performed with 24 biological replicates.

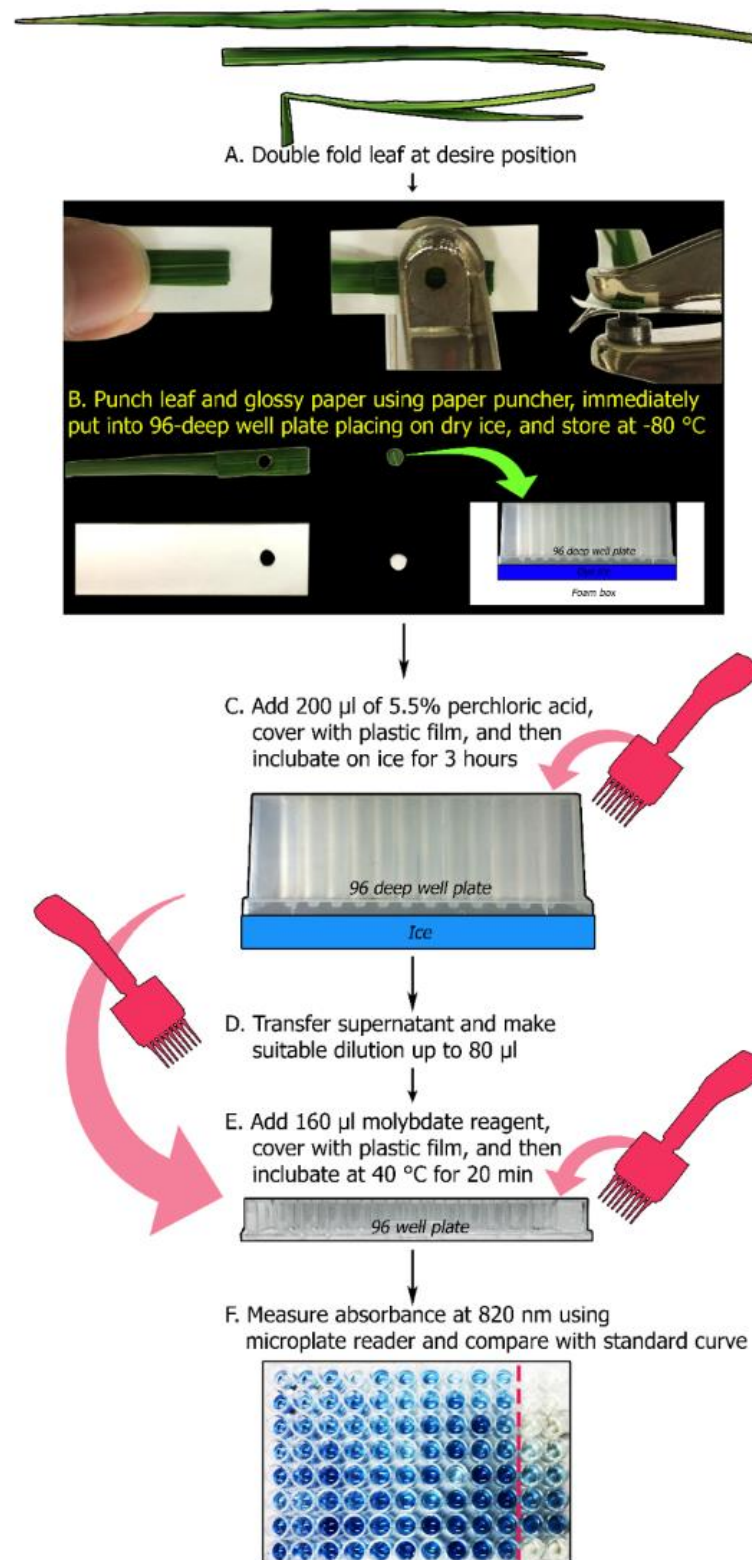

Figure 12 Steps of high-throughput punching method, Pi extraction, and measurement. The leaf was folded in half twice for providing fast tissue harvesting,

then put on glossy paper (A). Both leaf and paper were punched together to produce four-leaf discs at once. The glossy paper functioned as supporting soft leaves and avoiding leaf discs from sticking in the punching hole. Then the leaf discs were suddenly put into a 96-deep well plate, which was placed on dry ice to prevent hydrolysis of organic P. The plates with leaf samples were covered with aluminum foil and then kept at $-80\text{ }^{\circ}\text{C}$ until use (B). For extracting Pi content from leaf tissue, $200\text{ }\mu\text{l}$ of 5.5% (w/v) perchloric acid was added into each well of 96-deep well plate by using a multichannel pipette. The samples were submerged and incubated for 3 hours (C). The supernatant was then transferred to a new 96-well plate and diluted to suitable dilution with 5.5% (w/v) perchloric acid up to $80\text{ }\mu\text{l}$ of the final volume (D). For quantifying Pi content, $160\text{ }\mu\text{l}$ of Molybdate Blue reagent was added and then incubated at $40\text{ }^{\circ}\text{C}$ for 20 min (E). The absorbance was detected at 820 nm wavelength using a microplate reader. Pi content was compared with the P standard curve and analyzed with a leaf disc area (7.07 mm^2) as nmol/mm^2 (F).

2.1.4.3 Pi content detection in different leaf stages and positions

The first, second, third, and fourth fully expanded leaves of 24 day-old plants grown under 320 and $16\text{ }\mu\text{M}$ NaH_2PO_4 treatments of high Pi accumulator were cut into four sections equally. The leaf disc samples from each section were extracted and detected Pi content using the punching method. The experiment was performed with 12 biological replicates.

2.1.4.4 Statistical analysis

Analysis of variance (ANOVA) was performed, and the mean was compared with Duncan's Multiple Range Test (DMRT) by using IBM SPSS Statistics v. 22.

2.2 Phenotyping of local Thai rice cultivars under phosphorus deficiency at seedling stage

2.2.1 Plant culture and treatment

Seeds of 172 Thai rice (*Oryza sativa* L.) accessions, including local Thai rice varieties and breeding cultivars, were provided by the Pathum Thani Rice Research Center (**Table 4**). The seeds were surface sterilized and pre-cultured, as described in 2.1.1. Then, eight-day old seedlings without endosperm were transferred to 80-litter boxes containing full-strength Yoshida solution with different P supplements, including 320 (sufficient; S), 16 (mildly deficient; MD), and 0.8 μM NaH_2PO_4 (severely deficient; SD) for 16 days. The decrease of NaH_2PO_4 was replaced with an equal concentration of NaCl. The nutrient solution was renewed every four days and adjusted pH at 5.8 every two days (**Appendix E**). Each growth container contained all rice cultivars for equally nutrient acquired competition. The experiment was performed in a greenhouse with natural light (30-38°C day/26-30°C night temperature; 40-70 % day/70-90% night humidity; 11 h photoperiod of natural light (400-1,700 $\mu\text{mol m}^{-2} \text{s}^{-1}$) using the Randomized Complete Block design (RCBD) with three replicates. Each replicate contains three plants /cultivar.

2.2.2 Reflectance spectra measurement

After 16 days of treatments, the second fully expanded leaves were used for reflectance spectra measurement with non-imaging spectro-reflectometers, PolyPen RP 400 (UV-VIS) (**Table C1**). The device was calibrated with a white reference standard before use. Leaf adaxial was faced on the PolyPen's detector head to measure the reflectance from two points at the center of each leaf as the technical replicates. The hyperspectral reflectance of 320 – 790 nm wavelength was determined and exported from the device for future analysis as transmittance, computed using the formula below.

$$R_i = \text{Transmittance}_i = T_i = I/I_0$$

Where: I_0 is reference light intensity; I is measured light intensity

The same leaf sample was then cut as leaf discs using a paper puncher to be quantified Pi content using the punching method in **2.1.4.2**. Distribution and frequency plot of Pi content in each treatment were illustrated using Seaborn package v. 0.9.0 (Waskom *et al.*, 2014).

2.3 Analysis of spectral reflectance index in Thai rice under phosphorus deficiency and genome-wide association study (GWAS)

2.3.1 Spectral reflectance index analysis

2.3.1.1 Reflectance average and sensitivity

An average of reflectance was calculated and plotted against different spectral wavelength (nm) to distinguish the data characteristics of each treatment. The reflectance sensitivity on phosphorus deficiency was calculated as a percentage ratio between deficiency and sufficiency treatment as below.

$$\text{Reflectance sensitivity} = \left[\frac{(R_i \text{ of P deficient treatment} - R_i \text{ of the control})}{R_i \text{ of the control}} \times 100\% \right]$$

Whereas R_i = received transmittance value at the wavelength of 380, 382, 384,..., 790 nm (Zhao *et al.*, 2005).

The average and sensitivity plots were illustrated by using Seaborn package v. 0.9.0 (Waskom *et al.*, 2014).

2.3.1.2 Test of general spectral indices and the way for improvement

The collected reflectance data were calculated to generate 24 general vegetative indices, as described in **Table C2**. The computed data of the 24 general vegetative indices was tested and observed their property by performing the principal component analysis (PCA), hierarchical clustering analysis, and density plot. The PCA analysis and illustration were performed using Factoextra R package v.1.0.7 (Kassambara and Mundt, 2017). The hierarchical clustering was analyzed and visualized to observe the indices relationship by using Dendextend package v.1.0.1

(Galili, 2015). A density plot was visualized to investigate the deficiency effect in each different treatment by using Caret package v.6.0 (Kuhn, 2012).

I then calculated the mean normalized value of the indices by dividing between SD and S conditions. The mean normalized values of the 24 indices traits were associated with 113,114 SNPs from exome sequences of 172 rice accessions (Lekklar et al., 2019) using GEMMA software as fully described in **2.3.2**. The observation results were used to apply in the next step.

2.3.1.3 Spectral reflectance analysis and new developing indices

Correlation between each wavelength was calculated to observe self-correlation within the reflectance value by using a Spearman correlation model (SciPy package v.1.3.2) on Python (v.3.8.0). The new spectral reflectance indices were then established by the ratio of reflectance at two different wavelengths using NumPy package v. 1.17.4 (Harris et al., 2020).

$$\text{New spectral reflectance indices (NSR)} = R_{\lambda_j}/R_{\lambda_i}$$

Correlation between NSR indices and Pi content was performed using a Spearman correlation model in SciPy package v.1.3.2 (Virtanen et al., 2020). All analyses and illustrations were plotted using Seaborn package v. 0.9.0 (Waskom et al., 2014).

For providing the P deficient phenotype of NSR indices, the ratio between deficiency and sufficiency was calculated as relatively new spectral reflectance indices (RNSR). From the sensitivity result, the RNSR indices of the severely deficient level were selected for GWAS in the next step due to the significant response to P deficiency. In GWAS analysis, the mean data of RNSR indices were used every 10 nm of among reflectance spectrum range to reduce the amount of data in the analysis process.

2.3.2 Association analysis for phosphorus-deficiency responsive traits

The phenotypic data, including Pi content and 217 RNSR traits, were associated using linear mixed model via GEMMA software (Zhou and Stephens, 2012) with 113,114 single nucleotide polymorphisms (SNPs) derived from exome sequences (Lekklar *et al.*, 2019). Manhattan plots and QQ-plots were performed using qqman package v.0.1.4 (Turner, 2014). The visualization of significant SNPs against several spectral indices was illustrated using Seaborn package v. 0.9.0 (Waskom *et al.*, 2014).

2.3.3 Identification of phosphorus-deficiency tolerance genes

Significant SNPs were considered using Bonferroni correction with an experimental type I error rate of $\alpha = 0.05$, equivalent to a significant threshold $-\log(p\text{-value}) \geq 6.35$. Moreover, the SNP was also identified as significant if its location is within 100kb (upstream and downstream) of a Bonferroni's significant SNP.

CHAPTER IV

RESULTS

1. Development of a rapid inorganic phosphorus quantification

1.1 Optimization of incubation time

For developing a novel Pi quantification protocol, the conventional grinding method was considered three main problems; sample weighing, numerous pipetting, and grinding, which affected fastness and easiness in analysis. Thus, an alternative normalization by using leaf areas instead of leaf weight was proposed in this study. Paper puncher was applied to generate the equal-size leaf discs from each sample, which was used to normalize initial tissue used in the quantification. Moreover, a microplate reader and multi-channel pipettes were used to decrease time and material consumption. The grinding step was removed and replaced with the freeze-shattering technique to permeabilize the plant cell wall and release Pi out of the cell without grinding, and then immerse in extraction buffer.

For finding optimal incubation time for Pi extraction, homogeneously mixed leaf discs from high and low accumulator rice grown under P sufficient ($320 \mu\text{M P}$) or deficient ($16 \mu\text{M P}$) condition were kept at -80°C and incubated in 5.5% perchloric acid for various period times, 1, 2, 3, and 4 hours. The same mixed leaf discs were also extracted *via* the conventional extraction method. The supernatant was quantified using a molybdate blue reaction. The result showed that 3 hours of incubation indicated the comparable result of Pi extracted content as same as the conventional extraction method in both high and low Pi accumulation rice cultivars, and both P sufficiency and deficiency. Moreover, incubation time less than 3 hours is not enough to release all Pi from leaf tissue. Additionally, prolonged incubation of more than 3 hours led to increased Pi contents likely by hydrolysis of organic P (Figure 13).

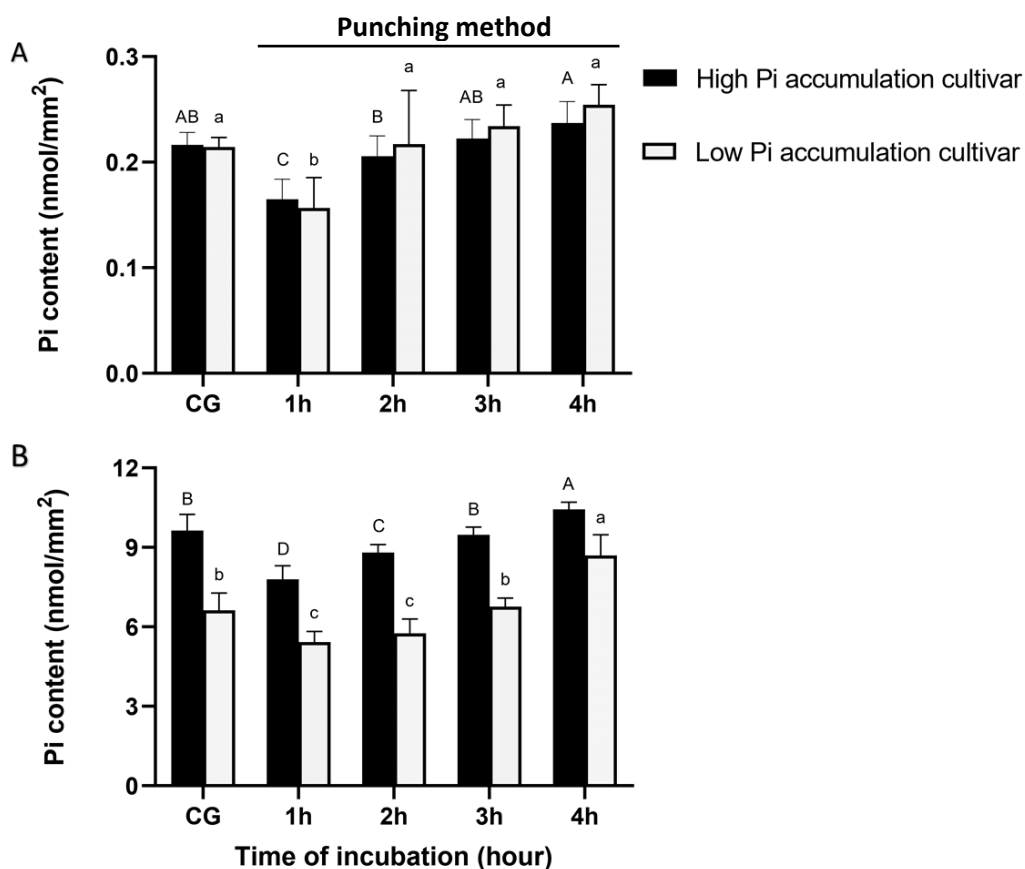

Figure 13 Effect of incubation time on soluble phosphate extraction via punching method comparing with the conventional grinding (CG) method in high and low Pi accumulators under phosphorus-deficient (A) and sufficient (B) conditions. Data are means \pm SD ($n = 10$). Different letters indicate significant differences ($P < 0.05$), according to Duncan's multiple range test (DMRT).

1.2 Validation of the punching quantification method

To validate the punching method, Pi content quantification via punching method was performed using leaf discs from second fully expanded leaves in low and high Pi accumulator under various five different levels of P supplement, and Pi content via conventional method was quantified by using residue tissues of the same leaves. The Pi content of the punching method and the conventional grinding method were normalized and calculated as nmol/mm^2 (leaf disc area) and $\mu\text{mol}/\text{g}$ FW (leaf fresh weight), respectively. For comparing the result in the comparable unit,

Pi content from the punching method was converted from nmol/mm^2 to $\mu\text{mol}/\text{g}$ FW unit by using the average fresh weight of a leaf disc (**Table B1**).

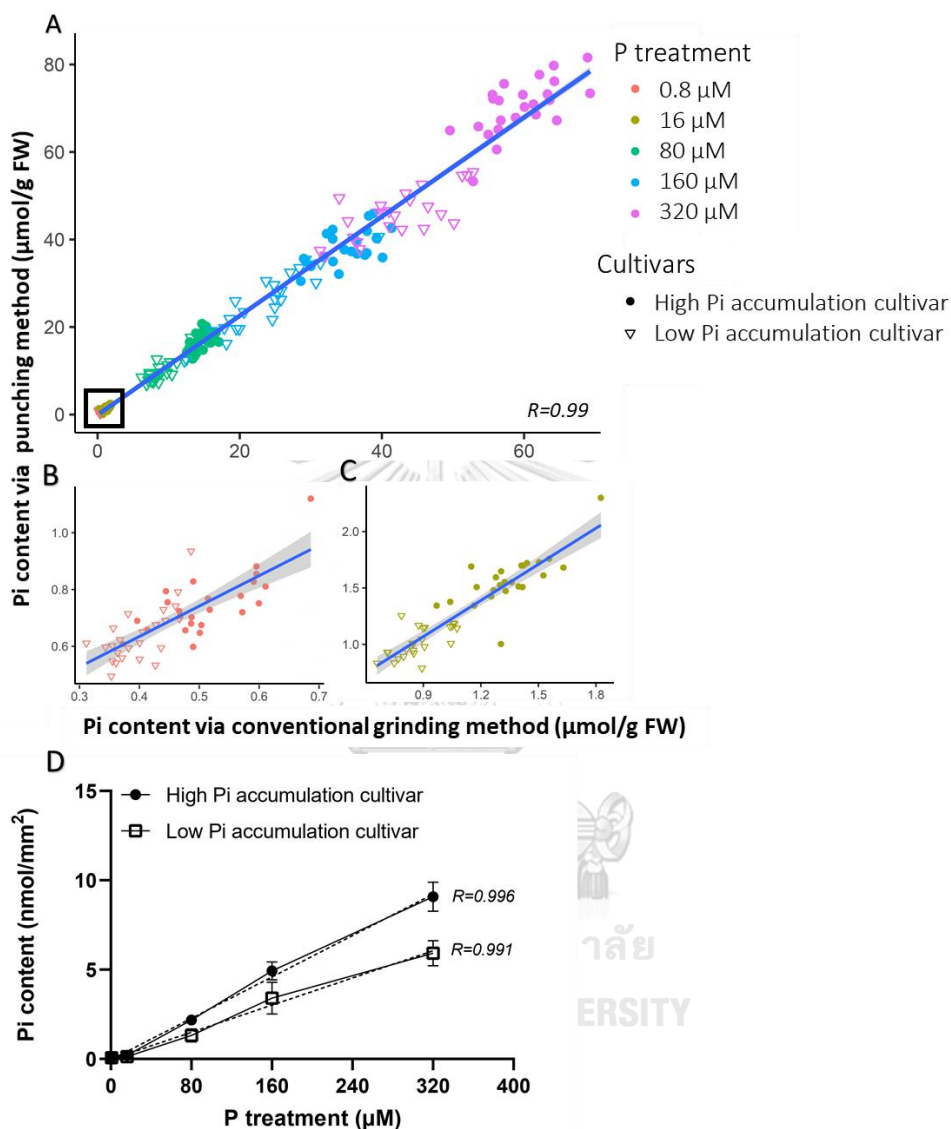

Figure 14 Pi contents of high and low Pi accumulation cultivars grown under different P supply (320, 160, 80, 16, and 0.8 μM P). Linear regression plots of Pi contents determined by punching method (y-axis, $\mu\text{mol}/\text{g}$ FW) and conventional grinding method (x-axis, $\mu\text{mol}/\text{g}$ FW) (A-C). Data points of plants grown under different levels of P supply (320, 160, 80, 16 and 0.8 μM P) (A), inset shown for 0.8 μM P (B) and 16 μM P (C). Graph showing the average of Pi contents was determined by punching method and fitted by linear regression (D). Data are means \pm SD ($n =$

24). Correlation (r) is determined by Pearson's correlation model. Statistical analyzes were performed with IBM SPSS Statistics ver. 22 and R program.

Comparing the two methods showed comparable Pi content with a high correlation of linear regression ($r=0.99$; when considered with all P supplement level) (**Figure 14A**). Furthermore, correlations (r) of 320, 160, 80, 16 and 0.8 μM P treatment were 0.92, 0.92, 0.92, 0.90 and 0.78, respectively (**Figure 14A-C**). The result indicated that the punching method yielded similar and reproducible results with the conventional grinding method in various P treatments. However, low level of P supplement of 0.8 μM P showed reduced correlation, which might be an effect from limited Pi in analyzed leaf tissue, as the plants displayed chlorosis symptom and stunted growth. To avoid this limitation, increasing leaf discs could be applied to increase Pi in the analysis, and the number of leaf discs could be used to normalize the Pi content. I also tested the linearity of the extraction by increasing the leaf disc number. High correlation between number of leaf discs and Pi content detected ($r=0.99$) suggested that the multiplication of leaf disc in the extraction did not affect the quantification (**Figure 15**). In addition, a comparable result ($r=0.97$) of the punching method with the inductively coupled plasma (ICP) quantification was tested to confirm the sensitivity of the novel method (**Figure B1**).

The accumulated Pi content in plant tissues was directly related to P concentration in the media solution (**Figure 14D**). By using the punching method, Pi content of the second fully expanded leaves was directed variation with Pi supplement level. Both high and low Pi accumulators showed a high correlation (r) with 0.996 and 0.991, respectively. The result presented that when P in the nutrient solution was increased, the plant also raised its accumulation and stored in their leaves. Moreover, high Pi accumulation cultivar showed higher accumulation ability than low Pi accumulation cultivar at all treatments tested.

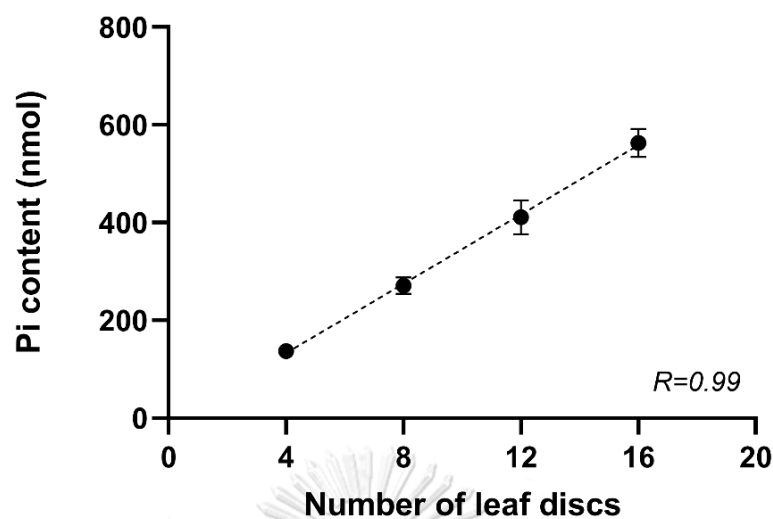

Figure 15 Linearity of the punching method. Graph showing Pi contents (nmol) determined from extracts with varying leaf disc numbers (4, 8, 12, 16 discs) and fitted by linear regression. Correlation (r) is determined by Pearson's correlation model using R software. Each sample was divided from the same pool of leaf discs derived from P-sufficient plants. Data are means \pm SD ($n = 8$).

1.3 Pi content detection in different leaf stages and positions

One of the advantages of the punching method is that the quantification process only needs a small area of leaf tissue that I can apply in any narrow and specific rice leaf position. I tested four different positions, along with leaf length from leaf base to leaf tip, and four different leaf stages applied the punching method to quantify Pi content in different leaf positions and leaf numbers under both P sufficient and deficient conditions (**Figure 16**). The testing indicated that Pi content was accumulated at the leaf tip lower than the leaf base under P sufficient condition ($320 \mu\text{M}$). Moreover, the older leaf stage (fourth fully expanded leaf) was found as a higher storage location than the younger leaves. The distribution of Pi content in each leaf position and stage illustrated the gradient concentration of Pi accumulation in the leaf. On the other hand, when P starvation occurred ($16 \mu\text{M}$), no significant difference in Pi content among leaf positions was found. However, Pi content in

various leaf stages still showed significant variation, but in the different accumulation patterns. Pi content in the youngest leaves (first fully expanded leaf) was more detectable than older leaf stages, caused by a remobilized and re-translocated property that helps the plant transfer limited P content from older leaves to the younger leaves.

Figure 16 Effect of leaf stages and positions of high Pi accumulation cultivar. (A) Rice leaves were punched at different positions. (B-C) Pi contents of rice grown under phosphorus sufficiency (B) and deficiency (C). Data are means \pm SD (n = 12). Different letters indicate significant differences ($P < 0.05$), according to Duncan's multiple range test (DMRT). Statistical analyses were performed with IBM SPSS Statistics ver. 22.

2. Phenotyping of local Thai rice cultivars under phosphorus deficiency at seedling stage

2.1 Phenotyping of rice using Pi quantification and hyperspectral detection

To test for phenotypic variations in the rice population and interaction of destructive and non-destructive measurements of Pi deficiency responses, I determined Pi contents and spectral reflectance in the second fully expanded leaves of 172 rice accessions grown under sufficient (S, 320 μM P), mildly deficient (MD, 16 μM P) and severely deficient (SD, 0.8 μM P) P conditions (**Figure 17**).

Figure 17 Experimental outline of the GWAS experiment.

In the quantification of Pi content, the leaf tissues were extracted and quantified *via* the punching method to obtain P deficient effect in each different Pi supplement level. The data of Pi contents in various cultivars are shown in **Table B2**. Pi content density and frequency distribution plot against the different concentrations showed a significant decrease of Pi content in various P treatments (**Figure 18A**). The frequency distribution showed quantitative and continuous information. The general trends of the Pi content parameter indicated the normal distribution that might be affected from polygenes in the plant. Moreover, Pi contents in each P treatment were not overlapped and the Pi levels depended on the P supply. These suggested that Pi content in plant tissue was obviously affected by the deficiency level of culture solution. The result suggested that Pi content should be a useful representative parameter to identify phosphorus-deficiency status, which is confirmed by the previous report that Pi content was a sensitive parameter to determine phosphorus-deficient status and indicated plant tolerant efficiency under phosphorus-deficient stress (Misson *et al.*, 2005).

Figure 18 Frequency distribution of Pi content (A), average reflectance spectrum (B) in three different phosphorus treatments (including sufficient (S), mildly deficient (MD), severely deficient (SD)), and sensitivity index (C) of normalized MD and SD treatment with S condition.

For leaf hyperspectral reflectance parameters, the same area used in Pi content quantification was used to measure spectral reflectance along 380-790 nm of the wavelength spectrum. P deficiency affected the increase of visible reflectance spectra and decreased NIR reflectance spectra (**Figure 18B**). Moreover, different deficiency levels influenced the different responsive effects. The MD treatment showed a less sensitive P deficiency response than SD treatment and looked similar to the S condition.

The P-deficient sensitivity was calculated to represent P response in each reflectance spectrum compared with the control (S) treatment. The result showed that SD treatment showed greater responses to P deficiency than MD treatment (**Figure 18C**). The sensitivity plot showed three peaks within visible and red edge regions (500-700 nm), in which the most sensitive region was located at 510, 637, and 691 nm. Moreover, two negative sensitivity regions were observed after 730 nm (NIR) wavelength and at around 400 nm or blue reflectance spectrum. The responsive regions of positive and negative sensitivity were focused on their response character to P deficiency in rice.

Though the MD-treated plants had much lower Pi contents than the S-treated plants (**Figure 18B-C**), they did not show apparent visible symptoms in leaf spectral reflectance. This result suggests that the P-deficient response phenotype in rice can be significantly detected *via* the hyperspectral approach when plants were grown under the SD condition but not the MD condition. However, leaf Pi contents quantification is a more sensitive technique to detect P deficiency response when plants were grown in mildly deficient treatment.

2.2 Analysis of spectral reflectance indices

First, different vegetative indices reported by the PolyPen spectrophotometer were evaluated. These included 24 vegetative indices, as described in **Table C2**. To observe the performance of each index, distributions of

each of the 24 indices determined from plants grown under different P treatments were visualized by density plots. Most of the indices did not show a differential response result in MD treatment, compared to the S treatment. Some indices, including GM1, GM2, NPQI, PRI, Ctr1, Ctr2, NDVI, SR, and ZMI, showed differential responses, (**Figure 19**). To observe similarities among the indices, a hierarchical clustering was performed. I found that most of the responsive indices were grouped due to a similar spectral data pattern (**Figure 20**).

Figure 19 Density plots of 24 general vegetative indices. The color lines determine reflectance data from S (green line), MD (blue line), and SD (pink line) treatment.

Next, traits from the vegetative indices were used to perform genome-wide association studies. The mean normalized values of the 24 indices were calculated by dividing the index value of the SD treatment by that of the S treatment and used for association mapping with 113,114 SNPs from exome sequences of 172 rice accessions (Lekklar *et al.*, 2019) using GEMMA software (Zoubarov *et al.*, 2012). The association result showed that only five indices, including GM1, GM2, NDVI, SR, and ZMI, resulted in identification of significant SNPs (**Figure 20**). Interestingly, these indices were also shown to be responsive to P deficiency, which could estimate P

response among treatments and had a close relationship of data in the hierarchical clustering (**Figure 21**). Furthermore, these indices were calculated from ratios between NIR wavelength and VIS wavelength, suggesting that the NIR and VIS spectral ratios are relevant to plant responses to P deficiency. Thus, the NIR and VIS spectrum ratio was used to generate new spectral reflectance indices (NSR) in the next step.

Figure 20 Comparative Manhattan and Q-Q plots on GWAS of normalized GM1 (A), normalized ZMI (B), normalized GM2 (C), normalized SR (D), and normalized NDVI (E)

with P deficient treatment. For Manhattan plots, the x-axis represents SNP positions across the entire rice genome by chromosome, and the y-axis is the $-\log_{10}$ p-value of each SNP. Red lines indicated the threshold line at $-\log(P\text{-value}) \geq 6.35$.

2.3 Hyperspectral analysis and index development

For considering relationship between spectral reflectance and Pi content, the Spearman's correlation between reflectance data at two wavelengths of each spectrum (self-correlation within spectrum) was calculated using SR data from the rice accessions grown under three different P supplements. The correlation matrix heat map displayed that the high self-correlations were found in two regions within visible and NIR zones, respectively. The high self-correlation within the big visible zone was located between spectral reflectance at wavelengths of ~420-720 nm and spectral reflectance of the other wavelengths ($r^2 = 0.53-0.99$), particularly between 500-650 nm ($r^2 = 0.61-0.99$) (Figure 22A, only data points at every 10 nm were shown). Another small NIR zone with high self-correlation was illustrated between spectral reflectance at wavelengths within ~730-780 nm and spectral reflectance at the other wavelengths ($r^2 = 0.91-0.99$). But interestingly, spectral reflectance at wavelengths in the NIR range (~730-780 nm) showed a low correlation ($r^2 = 0.05-0.54$) with spectral reflectance of the other wavelengths in the visible spectrum.

Although spectral reflectance at the range of 380-410 nm also showed low correlation with any wavelength measured (380-790 nm), they still had those of the adjacent wavelengths (e.g., within 10 nm). This implies that the reflectances at the 380-410 nm wavelength is noisy and might not suit for application in this investigation. Thus, they were not considered in this analysis.

Figure 21 Cluster heat map of 24 different vegetative indices. The hierarchical clustering was performed using values of all 24 vegetative indices. The left-colored y-axis represents S (green), MD (yellow), and SD (red) treatment. The X-axis represents 24 vegetative indices (red box indicates the potential and closed correlation indices). Red and blue colors in the heat map represents a negative and positive value, respectively.

Figure 22 Matrix correlation between its reflectance wavelength (self-correlation) (A) and matrix correlation between each reflectance index with Pi content (B). Blue line indicates the selected area.

Thus, the two ranges of potential spectra, including the visible range (R_{VIS}) and the NIR range (R_{NIR}), were considered from the spectral reflectance information of the full spectrum (420-790 nm). Ratios between two different spectral types of reflectances (R_{NIR} / R_{VIS}) were calculated for further analysis by using only SR values at every 10 nm (e.g., R_{420} , R_{430} , ..., R_{790}) to decrease the amount of data in the analysis. A total of 217 indices were generated and called New spectral reflectance indices (NSR) by pairwise analysis of the dividing ratio between 7 R_{NIR} (R_{730} , R_{740} , ..., R_{790}) and 31 R_{VIS} (R_{420} , R_{430} , ..., R_{720}) values.

Spearman correlation analysis between each of the 217 NSR indices and leaf Pi content measured from the same leaves was performed to estimate the

interaction between NSR ($R_{\text{NIR}}/R_{\text{VIS}}$) indices and leaf Pi content. The data were derived from a total of 172 rice accessions grown under MD and SD conditions. A correlation matrix heat map showed that the significant correlation ($r^2 > 0.69$) with leaf Pi content appears in the indices with the range of 730-790 nm (λ_{NIR}) and indices with the range of 530-630 nm or 700-720 nm (λ_{VIS}) (**Figure 22B**). The whole correlation matrix heat map was provided in **Figure B2**. The results indicate that the NSR ratio indices between 730-780 nm (NIR spectra) and of 530-630 nm (green to red spectra) or 700-720 nm (red edge spectra) could potentially be used to predict Pi contents in rice leaves. In P-sufficient leaves (S treatment), the ratio NSRs did not indicate a meaningful association with the leaf Pi content and were thus omitted from the evaluation.

Additionally, to check for false positives, I reordered the dataset to destroy data structure. The randomized dataset was used to calculate self-correlation and correlation with Pi content. The result showed that the self-correlation matrix and the correlation matrix with Pi content showed low correlation (**Figure B3**). The randomized dataset showed the significance of the data structure compared with the original dataset. The result and interpretation of data are not likely due to false positives.

2.4 Genome-wide association mapping of Pi content and hyperspectral indices

For the Pi content association, the mean Pi content measured from leaves grown under different P supplement (Pi_S, Pi_MD, and Pi_SD) were associated with 113,114 SNPs derived from exome sequences of 172 rice accessions using GEMMA software. The significant SNPs were considered using the threshold cutoff at $-\log_{10}(p) > 6.35$. The significant SNPs were classified as one association signal (locus) by grouping SNPs located approximately within 300 kb. The lowest P-value SNPs were considered as lead SNPs. The results showed that six loci were associated the

Pi_MD trait. The details of these loci are listed in **Table 5** . In contrast, the associations of Pi_S and Pi_SD traits did not show any significant SNPs (**Figure B4**).

Table 5 Detail of loci associated with Pi content and Spectral reflectance indices

Trait	Loci name	Chr	Number of significant SNPs	Lead SNP position (bp)	(-logP)	Minor allele frequency
Pi_MD	qPi1	1	1	18,062,446	7.81	0.101
	qPi5	5	2	16,423,976	6.83	0.057
	qPi8-1	8	1	8,596,112	10.11	0.052
	qPi8-2	8	3	9,225,490	9.37	0.085
	qPi8-3	8	6	18,346,725	9.19	0.054
	qPi11	11	2	25,844,888	6.68	0.054
SR (740/560, 750/700)	qSR1-1	1	0, 2	11,321,950	6.71	0.06
	qSR1-2	1	0, 1	38,610,955	6.40	0.114
	qSR2	2	5, 4	1,002,248	7.94, 7.92	0.075
	qSR3-1	3	3, 1	24,458,607	6.69, 6.40	0.106
	qSR3-2	3	1, 0	27,448,860	6.39	0.062
	qSR6-1	6	29, 30	7,583,291	7.60, 7.41	0.194
	qSR6-2	6	0, 2	24,291,698	6.54	0.135
	qSR6-3	6	1, 1	26,513,707	6.77, 6.72	0.054
	qSR8-1	8	0, 1	8,596,112	6.47	0.052
	qSR8-2	8	4, 3	9,225,490	7.39, 7.41	0.085
	qSR11	11	5, 3	20,701,489	7.56, 7.47	0.062

Figure 23 Manhattan and Q-Q plots based on GWAS of Pi content (A), normalized 740/560 index (B), and normalized 750/700 index (C) under SD treatment. For Manhattan plots, the x-axis represents SNP positions across the entire rice genome by chromosome, and the y-axis is the $-\log_{10}$ p-value of each SNP. Red lines indicated the threshold line at $-\log(P\text{-value}) = 6.35$.

For NSR traits, the 217 ratio indices ($R_{\text{NIR}}/R_{\text{VIS}}$) from 7 R_{NIR} and 31 R_{VIS} were used as the phenotypic data. For representing the P deficiency response effect without the background variation, relative NSR (RNSR) indices were calculated by dividing the means of the NSR indices from SD treatment and S treatment. The MD treatment was not used in the association analysis because its reflectance spectrum did not demonstrate an apparent response to P deficiency (**Figure 18**). The associations were

performed using the same procedure for Pi content association. From 217 RNSR traits, 104 traits identified upto 48 significant SNPs (**Table 6**), while the other 113 traits did not show any significant SNP. The significant SNPs from each association were highly overlapped, which might be due to high correlations of the NSR indices (**Figure 23**). In detail, two groups of ratio spectral indices, including NIR/green to red spectra (530-630 nm) and NIR/red edge spectrum, with R_{740}/R_{560} and R_{750}/R_{700} index, yielded significant SNPs with the lowest p-value from each group, respectively. Hierarchical clustering of $-\log P$ -value of candidate genes derived from all indices association grouped the 77 significance of NIR/530-630 reflectance indices and the 27 significance of NIR/700-720 reflectance indices (**Figure 24**).

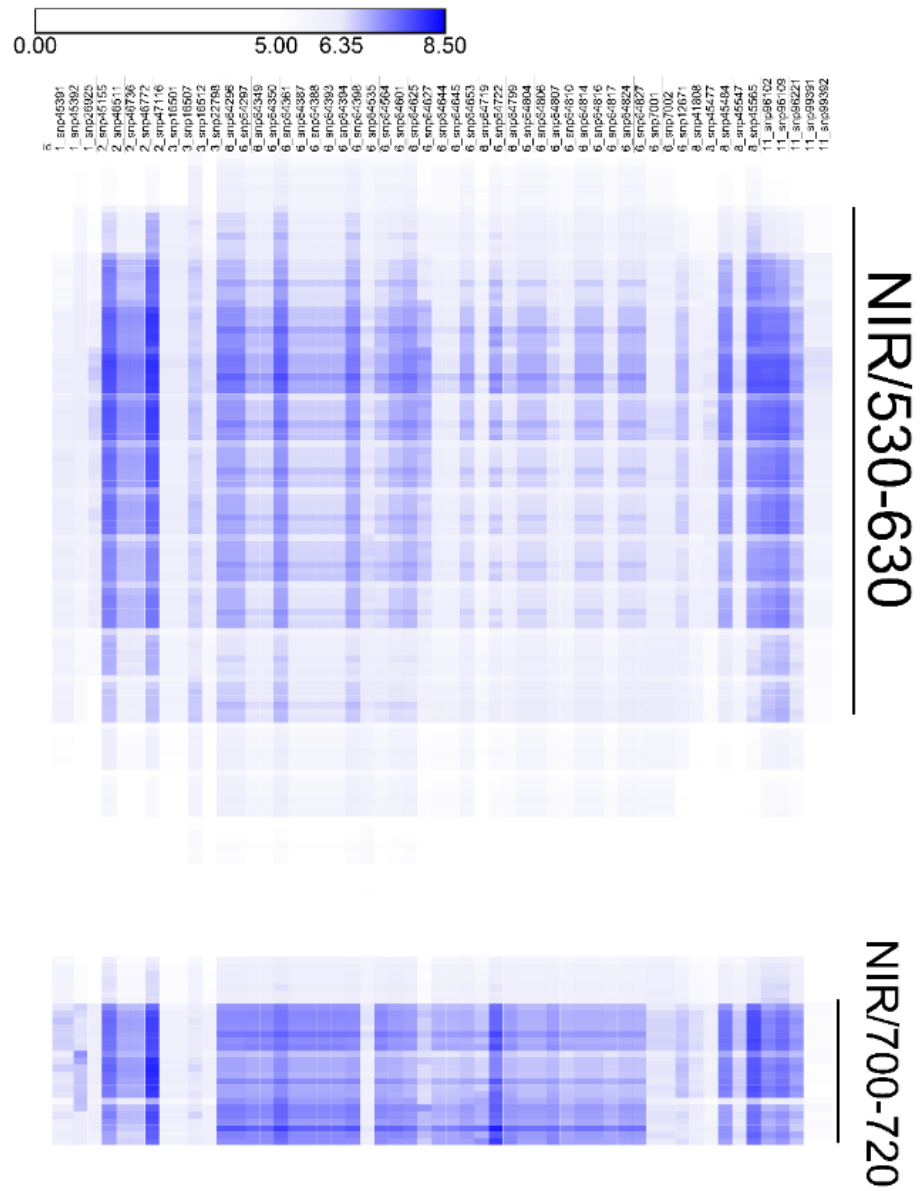

Figure 24 Heatmap of significant SNPs derived from spectral reflectance indices. Blue color represented a significant threshold at $-\log(\text{P-value}) \geq 6.35$.

Overall, 11 loci were summarized from all significant association SNPs of RNSR indices, which included ten loci of 48 significant SNPs derived from the trait R_{740}/R_{560} and seven loci of 48 significant SNPs derived from the trait R_{750}/R_{700} (**Figure 25**). Almost all of the significant SNPs (41 SNPs or 20 candidate genes) were the same between these spectral index groups. Only seven significant SNPs or four candidate genes of each were found to be specific in NIR/VIS group. Interestingly, three significant SNPs located in two candidate genes were found as SNPs identified in common from hyperspectral indices and Pi content traits.

Figure 25 Venn diagram representing the number of significant SNPs (or significant candidate genes in parentheses) from the association of Pi content, NIR/VIS (R_{740}/R_{560} index), and NIR/Red edge (R_{750}/R_{700} index) traits.

Heat maps showing $-\log$ p-value of two significant SNPs of *LOC_Os08g15330* and *LOC_Os08g15230* from all of the 217 RNSR traits indicated that the wide range of RNSR indices were also associated with the significant SNPs with p-values passed the threshold cutoff (**Figure 26**). Not only SNPs located in these two genes but the potential SNPs in the other ten genes were also associated with a similar trend (**Figure B5**). In addition, the significantly associated region of these two SNP heat maps overlapped with the high correlation zone of the spectral reflectance and Pi content. Such patterns suggest that the identified SNPs are likely not a false positive from noisy data.

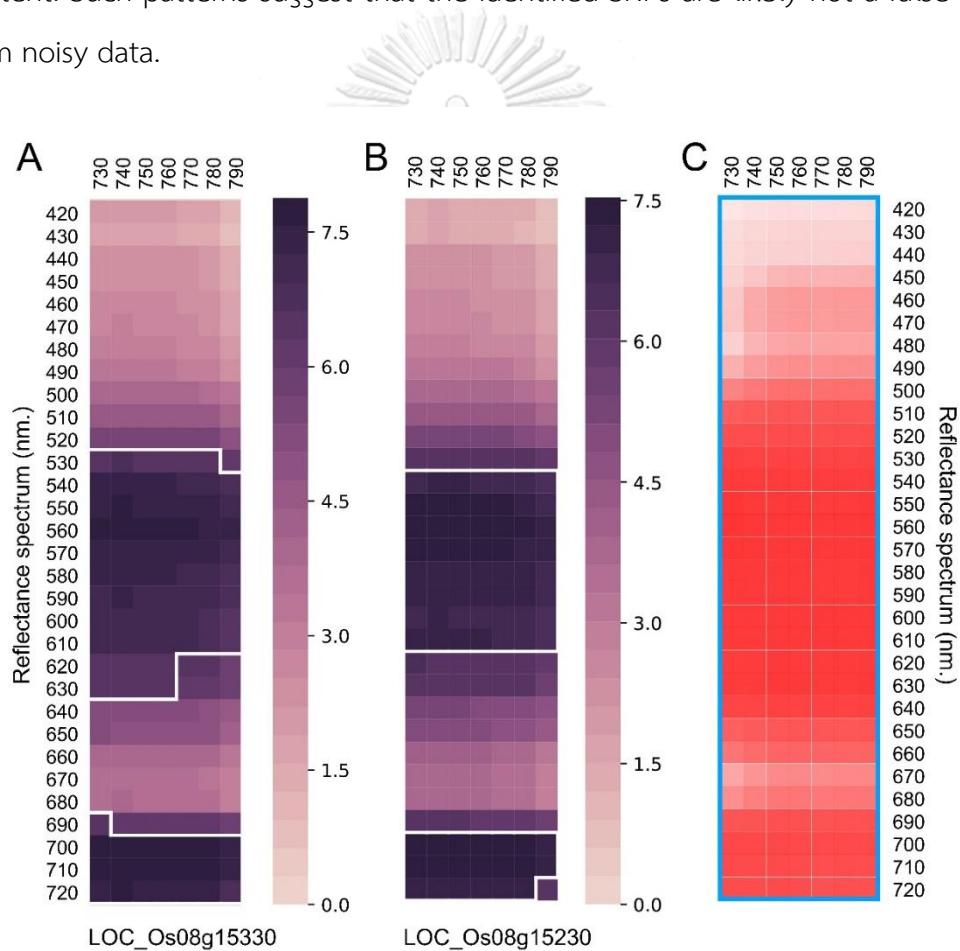

Figure 26 Heat map representing $-\log$ P-value of *LOC_Os08g15330* (A) and *LOC_Os08g15230* (B) significant candidate genes comparing with heat map showing correlation between the indices and Pi content (C). The surrounding white line indicated passed significant threshold line at $-\log(P\text{-value}) \geq 6.35$.

From the overlapped significant loci between Pi content and RNSR association, I found that the loci qSR8-1 and qSR8-2 were co-localized with qPi8-1 and qPi8-2, respectively. The candidate genes in the qPi8-2 and qSR8-2 regions encoded the suppressor of MAX2-like protein (*OsSMAX1*; LOC_Os08g15230) and anthocyanidin 3-O-glucosyltransferase (LOC_Os08g15330). The other 10 qSR loci are specific to the SR traits and the other 3 qPi loci are specific to the Pi traits. The highest candidate gene was found in the qSR6-1 locus that consisted of 30 significant SNPs located in 11 genes (**Table 6**).

From linkage disequilibrium (LD) analysis, several genes locating in the LD of significant candidate SNPs with $r^2 > 0.25$ was found (**Table 7**). Interestingly, a known gene related to P-deficient tolerance, *OsMYB4P* (LOC_Os11g35390) was found in LD block of qSR11 lead SNP ($r^2 = 0.84$). Moreover, two known genes involved to P response in Arabidopsis orthologues (*BiP2*; LOC_Os02g02410 and *AIR3*; LOC_Os06g40700), were identified in LD block of qSR2 and qSR6-2 ($r^2 = 0.64, 0.30$).

Table 7 List of LD linked candidate genes associated with Pi content and spectral reflectance indices.

CHAPTER V

DISCUSSION

1. Development of a rapid inorganic phosphorus quantification

The punching method has been tried to improve the conventional method to supply high throughput performance in Pi quantification. The process in punching method can be done without grinding, balancing, and several transferring steps with validation comparing to the conventional method. The Pi extraction could be finished within 3 hour-incubation time for both high and low accumulation rice cultivar grown under P deficient and sufficient condition (**Figure 12**). A total available Pi was extracted from the leaf tissue by using a freeze shattering technique without grinding step. Freezing plant organs or tissues affect orientation and distribution of microtubules along with plant cells, which release intracellular substance *via* permeabilization of the cell wall (Wasteneys *et al.*, 1997). This useful technique was applied to various types of materials and organisms (Tiwari and Polito, 1990; Braun, 1996; Wasteneys *et al.*, 1997). Another critical factor in Pi extraction is the incubation time of leaf tissues in the extraction solution. The 4 hours of incubation showed higher Pi content than the conventional process (**Figure 12**). The increased Pi content can be affected by intracellular enzymes, especially acid phosphatase, which converts organic P and structure binding P to detectable Pi content (Duff *et al.*, 1994; Tazisong *et al.*, 2015). Thus, time control and performing the process under low temperature help to avoid hydrolysis of organic P from the action of the phosphatase enzymes (Gundlach and Luttermann-Semmer, 1987).

Our validation showed that the punching method based on leaf area normalization and non-grinding approach has a comparable result to the conventional method using sample grinding and biomass normalizing processes. Normalization of the Pi content in root tissues with root length has been previously studied in *Arabidopsis* seedlings, which were grown on a one-dimensional agar plate (Ayadi *et al.*, 2015; Kanno *et al.*, 2016). The complex organs, which have a largely

various size or biomass of plant tissues (such as large root system or fruit), may not be appropriate for Pi content calculation by using area normalization techniques. Besides, it should be noted that accuracy may decrease when using this method for P-deficient samples. When I consider a leaf disc weight of high and low Pi accumulators grown under severely P supply levels, I found unequal leaf weight in the lowest P treatment (**Table B1**). Several studies reported P starvation affects growth and development in the plant, particularly leaf weight and area (HØGH-JENSEN *et al.*, 2002; Chaudhary *et al.*, 2008; Singh *et al.*, 2013). This evidence suggests that level of P deficiency should be considered for the application of this method in your experiment. A comparison between sufficient and severely deficient conditions, which decreases leaf weight or thickness, should be avoided to prevent error interpretation. Optionally, Pi content should be converted by normalizing with average leaf weight per leaf disc before the interpretation to remove the error effect of unequal amount of tissue used. Moreover, the punching method could be limited for small and narrow leaf phenotype in P deficiency condition, which is more difficult to handle with paper punchers. Thus, the level and treatment period of P starvation should be tested before Pi content analysis.

Pi content quantification results from a different position and stage in the same plant showed the various levels of Pi accumulation in the tissue (**Figure 16**). The result suggested that leaf position and stage are essential factors that should be considered to select leaf samples for the analysis. Based on the Pi content in different positions and stages in rice, less than 20 folds difference in Pi content between the plant grown under sufficient (320 μM P) and deficient conditions were detected. Moreover, various fold differences (21-33 and 125-177 folds) were found in the first leaf (youngest) and fourth leaf (older) stage, respectively. Different Pi accumulation in each part and position is controlled by complex regulation in Pi homeostasis to remobilize Pi content to the essential organ during the P starvation period (Irfan *et al.*, 2020). The remobilization of Pi content represents P used

efficiency adaptation in rice under P deficiency (Dissanayaka *et al.*, 2018). Thus, the researchers should carefully decide to choose a suitable leaf position and stage for their experiments. Although this punching method still has some limitation with scarce Pi content and is not optimized for other plant tissues, it can be a quick and easy procedure for initial screening of large number of rice materials and various treatments before validation with the conventional method.

The significant difference in Pi accumulation performance in these two rice cultivars showed the genetic ability to control different accumulation abilities in these rice (**Figure 14D**). Recently, phenomics studies have become popular and required to unravel the genetic function controlled agronomical traits by integration with the genomic platform. And this developed high-throughput method can be used for application in large-scale detection of Pi content in rice leaf among the big population of the genomic study.

2. Phenotyping of local Thai rice cultivars under phosphorus deficiency at seedling stage

2.1 Phenotyping of rice using Pi quantification and hyperspectral detection

Response phenotype of phosphorus deficiency in rice can be observed from various growth parameters, such as biomass, plant height, root length, etc. (Li *et al.*, 2009; Vejchasarn *et al.*, 2016; Chankaew *et al.*, 2019). However, they may not be obvious to detect P response during the seedling stage. Pi accumulation content in leaves was reported as a sensitive parameter to detect plant deficiency status in plants (Wissuwa and Ae, 2001; Misson *et al.*, 2005; Mehra *et al.*, 2016; Pereira *et al.*, 2020). Currently, hyperspectral measurement has been applied to various plants and purposes due to its sensitive, non-destructive, and rapid property (Bellante *et al.*, 2014; Kim *et al.*, 2015; Kuska *et al.*, 2018; D. Wang *et al.*, 2019). This study is a large-scale detection of rice response under P starvation by using Pi quantification and hyperspectral measurement to evaluate P deficiency effect and P used efficiency in

various rice cultivars. I hydroponically cultured 172 rice accessions in the seedling stage under three different phosphorus levels. The Pi content in the leaves at the same age was estimated *via* the punching method and hyperspectral measurement *via* the Polypen device. The intracellular Pi content in rice leaves grown under different P supplementation showed obviously distinguishing among P deficiency levels (**Figure 18A**). Pi content is decreased by the use in metabolism processes under P limit, including photosynthesis and cellular respiration (Mikulska *et al.*, 1998; Wang *et al.*, 2015), leading to P starvation in plants.

The Pi quantification refers to the available phosphorus in a plant that directly indicates the residual level of storage Pi content in the plants. In other words, the difference of residual Pi content in the rice population under starvation is controlled by genetic regulatory in the phosphorus homeostasis pathway (Lin *et al.*, 2009; Fabianska *et al.*, 2019) that refers to the variation of Pi used efficiency performance in this rice population. On the other hand, hyperspectral measurement is indirect detection that is not directly used to evaluate P content in the plants. But the hyperspectral approach focuses on the electromagnetic reflection from biochemical molecules such as chlorophyll, anthocyanin, carotenoid, etc. and it is used to distinguish plant response by comparison analysis between treatments. In the hyperspectral analysis, the significant P deficiency response can be observed in only SD treatment, in which the plants were grown in a very low P supplement. In contrast, MD treatment did not show a noticeable difference with sufficient conditions (**Figure 18B-C**). The appearance of the phenomenon in rice response to P deficiency may be due to the different levels of P starvation that affect occurrent P deficient symptoms (Yaseen *et al.*, 2000; Massawe and Mrema, 2017). The five spectral reflectance indices, GM1, GM2, NDVI, SR, and ZMI, represent the capable detection and predictivity in P deficiency response and gene identification, respectively (**Figures 19 and 20**). Interestingly, the indices were developed with a high correlation with chlorophyll content to classify green leaves from other objects

and help distinguish stress response in the various plants (Zarco-Tejada *et al.*, 2002; Zagajewski *et al.*, 2018; Caturegli *et al.*, 2020). The result similarly suggested as the previous reports that P starvation reduced biosynthesis of chlorophyll content and photosynthesis activity (Xu *et al.*, 2007; Hernández and Munné-Bosch, 2015). Most of the indices were generated by the dividing ratio between two reflectance spectra in NIR and VIS wavelength, representing the responsible value and used for generating detective indices in several stress-response observations. In this research, the newly generated NIR/VIS ratio indices represented meaningful and correlated results with Pi content (**Figure 21**). The application of spectral reflectance in P deficiency prediction has been done in some other plants such as grass (Bogrekci and Lee, 2005), rangeland plants (Özyiğit and Bilgen, 2013), soybean (Milton *et al.*, 1991; Guo, 2017), corn (Osborne *et al.*, 2002), and Tomato (G. Sun *et al.*, 2019). Different representative wavelength representing P content was used in different species, which mainly focused at green, red, and NIR spectrum. By their own algorithm and model calculation, different correlation coefficient between generated reflectance index and detected Pi content was found at 0.425, 0.43, 0.6172, 0.68, 0.91, respectively.

2.2 Genome-wide association mapping of Pi content and spectral reflectance indices

Among genome-wide association mapping of 217 spectral reflectance traits, the NIR/green to red (530-630 nm) and NIR/red edge (700-720 nm), which have a high correlation with Pi content, can predict significant SNPs with low P-value (**Figure 23**). These spectral regions are responsive to P deficiency in the plants with high correlation coefficient to leaf Pi contents. (Peng *et al.*, 2020). Particular the NIR/red edge indices, which were reported and applied to represent several stress responses (Barnes *et al.*, 2000; Furbank and Tester, 2011; Kim *et al.*, 2011), showed significant P-value of the predicted SNPs in the associations. However, the wavelength of the red edge is quite short (about 700-720 nm) that limited the measurement process by the sensitivity of the detective device. NIR/green to red indices similarly identified

significant SNPs. Thus, the NIR/green to red indices may be suitable to be determined with a low cost or DIY hyperspectral tools with high sensitivity (Abd-Elrahman *et al.*, 2011; Huang *et al.*, 2018; Zhao *et al.*, 2018; Ribes *et al.*, 2020).

Comparing significant SNPs between Pi content and spectral reflectance indices associations showed that the same locus and candidate genes were found on chromosome 8 (**Figure 22**). Two known genes, anthocyanidin 3-O-glucosyltransferase (LOC_Os08g15330) and *OsSMAX1* (LOC_Os08g15230), has been shown to be related to Pi deficiency responses (Secco *et al.*, 2013; Yin *et al.*, 2012), suggesting the performance of both Pi content and spectral reflectance indices traits in the prediction of genes involved in P deficiency response. The catalytic enzyme in the anthocyanin biosynthesis pathway, anthocyanidin 3-O-glucosyltransferase (EC 2.4.1.115) (Sun *et al.*, 2016), and its expression has been shown to be up-regulated by P deficiency in suspension-cultured grape cells studies (Yin *et al.*, 2012), consistent with P deprivation triggered anthocyanin accumulation (Jiang *et al.*, 2007; Ito *et al.*, 2015; Chen *et al.*, 2018). A recent study showed that *OsSMAX1* plays roles in the karrikin signaling pathway downstream of the Dwarf14-Like (D4L) Karrikin receptor and negatively controls arbuscular mycorrhiza (AM) symbiosis and strigolactone biosynthesis (Choi *et al.*, 2020), which are adaptive strategies to overcome P deficiency (Balzergue *et al.*, 2011; Lanfranco *et al.*, 2018). The symbiosis process was triggered by strigolactone hormone that had been highly accumulated in *smax1* knockout mutant during P deficient condition (Choi *et al.*, 2020).

Another interesting locus, qSR6-1, consisted of 30 significant SNPs located in 12 genes (**Table 6**). *LOC_Os06g13810* encoding the regulatory β -subunit of pyrophosphate-fructose 6-phosphate 1-phosphotransferase (PFP1b) was found in this locus. The PFP enzyme (also called PPI-dependent phosphofructokinase, PPI-PFK; EC 2.7.1.90) catalyzes the reversible phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate in the glycolysis pathway and involved in various stress response, including P deficiency and anoxia in which cytoplasmic Pi and ATP are

limited (Mertens *et al.*, 1990; Plaxton and Tran, 2011). Additionally, up-regulation of the *LOC_Os06g13810* gene under P deficiency has also been showed in transgenic rice overexpressing a novel transcription factor (*OsPTF1*) (Yi *et al.*, 2005).

Moreover, three of the LD linked candidate genes were previously reported to be involved in other P-deficient adaptation (**Table 7**). One of these genes is a known gene related to P-deficient tolerance, *LOC_Os11g35390* encoding R2R3-type MYB transcription factor, OsMYB4P, was identified in the qSR11 locus, whose overexpression in rice promotes Pi uptake by root system architecture adaptation and transporter up-regulation (W. T. Yang *et al.*, 2014). This gene is located in the LD block of qSR11 lead SNP with high correlation ($r^2 = 0.84$). In the LD block of qSR6-2 ($r^2 = 0.64$), *LOC_Os06g40700* encoding subtilisin in rice is an ortholog of *Auxin-induced in root cultures 3 (AIR3; AT2G04160)* gene, which was triggered by auxin to promote lateral root formation and thus facilitate lateral root emergence in *Arabidopsis*. This gene showed dramatic and stable up-regulation under P starvation (Al-Ghazi *et al.*, 2003; Hammond *et al.*, 2003). In the LD block of qSR2 ($r^2 = 0.30$), I also found an orthologous gene of *LOC_Os02g02410*, DnaK family protein in *Arabidopsis* called BiP2 (AT5G42020), which involved with ER stress response under P starvation. Under P deficiency condition, *AtBiP2* was dramatically increased in root tip to suppress ER stress and autophagy, which was consequently induced by ER stress and P starvation (Naumann *et al.*, 2019).

The candidate genes and their linked genes were checked with the microarray and RNA-seq datasets from several P deficiency experiments (Zheng *et al.*, 2009; X. Dai *et al.*, 2012; Gamuyao *et al.*, 2012; Secco *et al.*, 2013; P. Mehra *et al.*, 2015). Interestingly, I found that most of the candidate genes showed a response to P deficiency condition, suggesting that they might be involved in response to P starvation. There were nine candidate genes that showed up or down-regulation in both microarray and RNA-seq datasets (**Figure 27-30**); these include *LOC_Os02g02370* (myb-like DNA-binding domain protein), *LOC_Os03g43720*

(transporter family protein), *LOC_Os05g28090* (expressed protein), *LOC_Os06g13660* (alanyl-tRNA synthetase), *LOC_Os06g13680* (B12D protein), *LOC_Os06g13760* (glycosyl transferase8 protein), *LOC_Os08g15230* (SMAX1-like protein), *LOC_Os08g29854* (*RGH1A*), *LOC_Os08g30070* (expressed protein). I found eleven linked candidate genes that showed differential expression in P starvation treatments, including *LOC_Os01g66500* (phosphoribosylformylglycinamide synthase), *LOC_Os06g13600* (HEAT repeat family protein), *LOC_Os06g40750* (expressed protein), *LOC_Os06g40818* (aspartic proteinase), *LOC_Os08g14450* (RNA polymerase sigma factor), *LOC_Os08g29809* (resistance protein LR10), *LOC_Os11g35210* (NB-ARC domain-containing protein), *LOC_Os11g35710* (cycloartenol synthase), *LOC_Os11g42200* (laccase precursor protein), *LOC_Os11g42390* (Serine Carboxypeptidase), and *LOC_Os11g42430* (transporter family protein). A gene on chromosome 11 encoding transporter protein (*LOC_Os11g42430*) had strong up- and down-regulated expression in separated P deficient experiment, and also showed significant expression in root sample under P deficiency experiment of wild rice (*Oryza rufipogon* Griff.) (Deng *et al.*, 2018), which were previously reported as P deficient tolerance (Chen *et al.*, 2011).

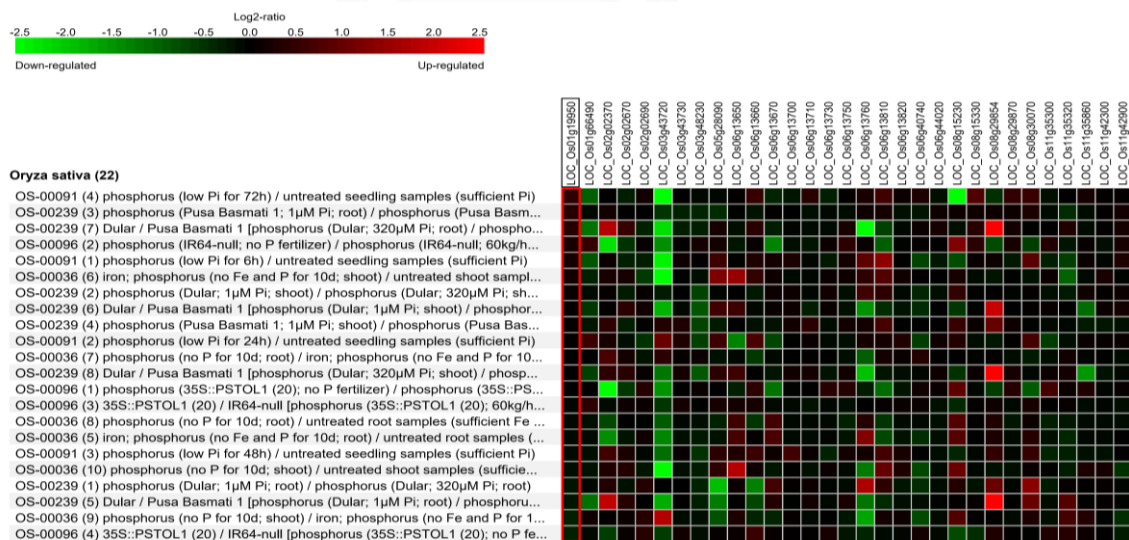

Figure 27 Gene expression heat map of the associated significant genes (rows) from several P deficiency experiments (columns) (Zheng *et al.*, 2009; X. Dai *et al.*, 2012;

Gamuyao et al., 2012; P. Mehra et al., 2015), Affymetrix Rice Genome Array platform from the GENEVESTIGATOR tool was used (Hruz et al., 2008b; 2008a). Down and up-regulation were represented by green and red colors, respectively.

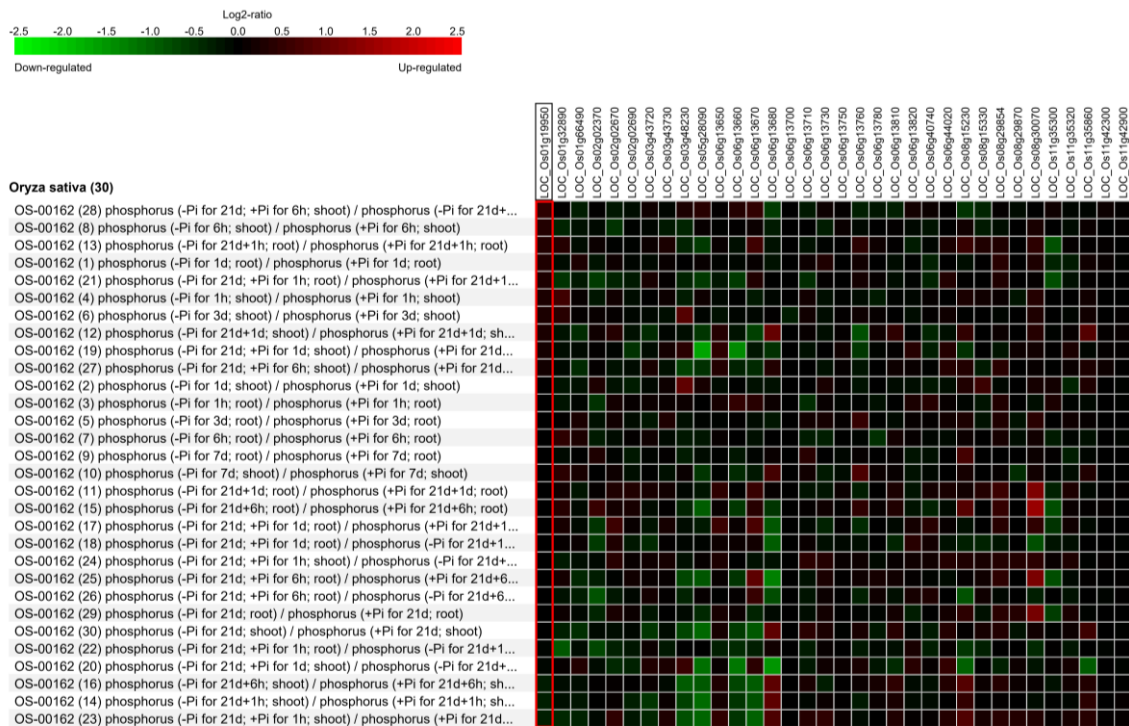

Figure 28 Gene expression heat map of the associated significant genes (rows) from several P deficiency experiments (columns) (Secco et al., 2013), the RNA-Seq platform from the GENEVESTIGATOR tool was used (Hruz et al., 2008b). Down and up-regulation were represented by green and red colors, respectively.

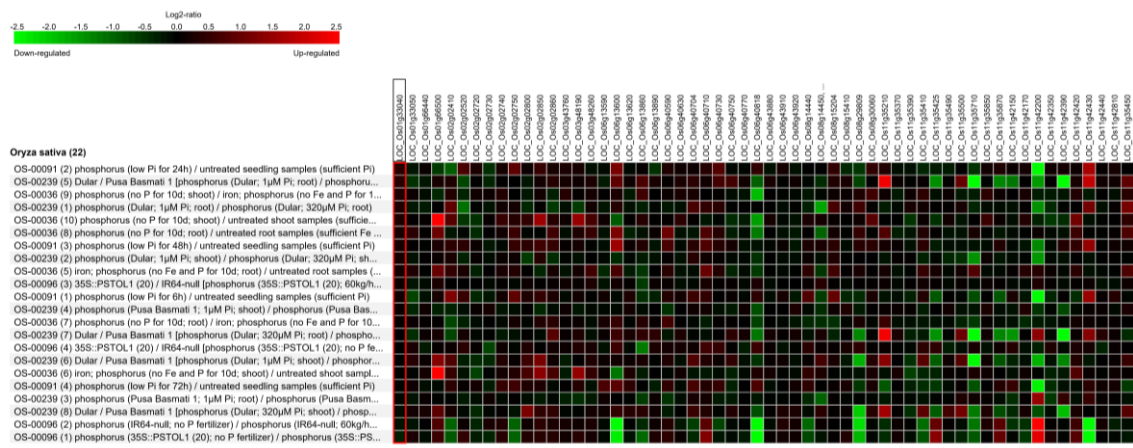

Figure 29 Gene expression heat map of the LD linked candidate genes (rows) from several P deficiency experiments (columns) (Zheng et al., 2009; X. Dai et al., 2012; Gamuyao et al., 2012; P. Mehra et al., 2015), Affymetrix Rice Genome Array platform from the GENEVESTIGATOR tool was used (Hruz et al., 2008b). Down and up-regulation were represented by green and red colors, respectively.

Figure 30 Gene expression heat map of the LD linked candidate genes (rows) from several P deficiency experiments (columns) (Secco et al., 2013), the RNA-Seq platform from the GENEVESTIGATOR tool was used (Hruz et al., 2008b). Down and up-regulation were represented by green and red colors, respectively.

Besides, some candidate genes co-localized with P deficiency-related QTLs, which related to P responsive phenotypes (**Figure 31**). The candidate genes are located on six chromosomes, including chromosome 1, 2, 3, 6, 8, and 11. Particularly, chromosomes 3 and 6, some of candidate genes were within the reported P deficiency QTL (Ni *et al.*, 1998; Wissuwa *et al.*, 1998; Li *et al.*, 2009; Jewel *et al.*, 2019). Three candidate genes are located within qRN3 and qRFW3a (RM6832-RM3513) on chromosome 3, which are related to root and root fresh weight phenotype. Moreover, another three genes on the same chromosome within qRFW3b and qRRN3 (RM2334-3166) were also detected, which control root-fresh weight and relative total root number under P deficiency condition, respectively. Additionally, 13 candidate genes located within qPH (RM7269-RM5314) on chromosome 6 represent plant height traits grown under P deficiency condition. Moreover, 19 candidate genes are located near qMRL6b (RM402-RM7023) on chromosome 6, which involved with maximum root length phenotype. Twelve candidate gene on chromosome 2 were found near the position of qAE_2.1 marker (SNP_2_542635) that contributed to agronomic efficiency response under P limited condition. , Eight candidate genes on chromosome 8 are located near qPFP_8.2 (SNP_8_8437588) that involves in partial factor productivity in rice. Another group of 7 candidate genes on chromosome 8 located near qRN8a (RM1309- RM1109B), which involved total root number parameter, which is important to forage available phosphorus in soil. Finally, 15 candidate genes are located near qRS11 (RM5349-RM21) involved in the root-shoot ratio under P starvation treatment.

Figure 31 QTL mapping of significant candidate genes and previous P responsive QTL positions. Lines and dots represent P responsive QTL intervals and SNPs from previous reports, respectively. The color symbols include red (Li et al., 2009), green (Ni et al., 1998), blue (Wissuwa et al., 1998), and yellow (Jewel et al., 2019).

Besides, gene expression under P deficiency from several reported experiments of all association candidate genes shows the high response in several predicted genes that also includes known P responsive genes. Moreover, some groups of candidate genes are also in the reported QTL region (Ni et al., 1998; Wissuwa et al., 1998; Li et al., 2009; Jewel et al., 2019) (**Figure 31**). These indicate potential candidate genes that may involve and regulate P deficient tolerance and regulation in rice. In candidate gene identification process, function-dependent strategy and position-dependent strategy were mainly considered to identify the potential candidate gene (Zhu and Zhao, 2007). Gene expression pattern of some gene can be modulated by some specific environmental factor, such as *PSTOL1* that

is induced by phosphorus-deficient condition (Gamuyao *et al.*, 2012). Moreover, physical linkage in QTL segment can be provided positive gene (Van Laere *et al.*, 2003), although application of position-dependent strategy could not be guarantee with high accuracy, due to many false-positive, but it can hint to narrow down the potential region (Zhu and Zhao, 2007; Lekklar *et al.*, 2019). From the gene expression and location on reported QTL studies, some genes have high potential on function in P deficiency regulation in rice.

LOC_Os02g02370 (myb-like DNA-binding domain protein; OsMYB61) is one member of the MYB transcription factors, which regulates and involves several plant regulation and abiotic stress response (Katiyar *et al.*, 2012). The orthologue overexpression *Arabidopsis* showed enhancement of root system architecture and resource allocation (Romano *et al.*, 2012). Several R2R3-MYB genes are involved in controlling responses to P deficiency in *Arabidopsis* and rice, including *AtMYB62* (Devaiah *et al.*, 2009), *AtMYB103* (Yu *et al.*, 2019), *OsMYB2P-1* (Xiaoyan Dai *et al.*, 2012), *OsMYB5P* (Yang *et al.*, 2018), and particularly *OsMYB4P* (W. T. Yang *et al.*, 2014) which also found in this association.

CAS1 gene (LOC_Os11g35710) encoded an important cycloartenol synthase enzyme, which converts isopentenyl pyrophosphate to cycloartenol. The cycloartenol is the key essential compound for multistep brassinosteroid biosynthesis (Bajguz *et al.*, 2020). Brassinosteroid is an essential plant hormone involving in plant development, several stress responses (Planas-Riverola *et al.*, 2019), and particularly the deficiency of nitrogen (Y. Wang *et al.*, 2019), boron (Zhang *et al.*, 2019), iron (B. Wang *et al.*, 2012), and phosphorus (Singh *et al.*, 2014). In rice, brassinosteroid is an important signaling factor regulating P deficiency-induced leaf inclination to decrease excess light reception (Ruan *et al.*, 2018; Zou *et al.*, 2020).

The NiaP transporter encoded gene (LOC_Os03g43720) provides nicotinate transporter in plants (Jeanguenin *et al.*, 2012). Nicotinamide is a part of the NADH

and NADPH that important in energy metabolism. P deficiency affects reduced photosynthesis and photorespiration rate (Terry and Ulrich, 1973). Moreover, NADPH and NADH levels are increased to maintain energy homeostasis (Carstensen *et al.*, 2018).

An EF-hand family member or calmodulin-like gene (*LOC_Os06g40720*) is a regulatory member of second messenger calcium (Ca^{2+}) that involves in plant signal transduction various stresses, including P deficiency (Hernández *et al.*, 2007). The obvious calcium signaling in *Arabidopsis* root is dramatically triggered by P starvation but not by N starvation and correlates with a high level of reactive oxygen species (ROS) (Matthus *et al.*, 2019). *AtPsiCaM* (*Arabidopsis* Pi-starvation-induced CaM) had been proven for the interaction between P deficiency and the calmodulin signaling pathway in *Arabidopsis* (Duan *et al.*, 2005).

Two-component response regulator (*LOC_Os06g43910*) or *Arabidopsis* response regulator (ARR12) orthologue plays a key role in cytokinin signaling (Argyros *et al.*, 2008). The *AtARR12* is the phosphate starvation response protein target. Its expression is upregulated under P deficiency (Bustos *et al.*, 2010). ARR12 is a member of network regulation in root response to P deficiency by regulation of P signaling, auxin, gibberellin, and cytokinin hormone (Crombez *et al.*, 2019).

Less tillering is one of the response plant phenotypes under P starvation (Li *et al.*, 2003). The associated gene, *MONOCULM 1* (*OsMOC1*; *LOC_Os06g40780*) or *AtLAS* in *Arabidopsis*, plays a role in tillering formation by the initiation of meristematic axillary bud (Zhang *et al.*, 2020). *AtLAS* is controlled by SQUAMOSA-PROMOTER BINDING PROTEIN LIKE 9 (SPL9) and microRNA156. Interestingly, *AtSPLs* and microRNA156 are also regulated by P starvation (Lei *et al.*, 2016). Thus, this functional link between these studies makes high confidence in the candidate gene in P deficiency regulation.

CHAPTER VI

CONCLUSION

1. Novel Pi quantification method has been developed.

This study developed the punching method, which provided high throughput quantification based on the conventional Pi extraction and molybdate blue colorimetric assay. The method assisted in processing thousands of samples within 3 hours performing only one researcher. The punching method can be applied in large scale quantification that answers highly quantificational demand in phenomics and genomic study.

2. Hyperspectral reflectance indices can reflect Pi content under P deficient condition and they can be used for GWAS.

Among the 172 rice accessions and three P concentrations, Pi content is a very sensitive parameter that can detect the internal P deficient status within the plant of all the three different P treatments. On the other hand, hyperspectral measurement is clearly detectable in only the severely deficient treatment. I provided R_{740}/R_{560} and R_{750}/R_{700} indices as informative spectral reflectance indices representing the P deficiency phenotype in rice. Moreover, these indices can be used to apply in the genomic study by strong correlation with Pi content.

3. Based on exome sequences of 172 Thai rice cultivars, GWAS with hyperspectral indices can identify more causative genes for P deficient response than Pi content.

In this study, 30 candidate genes were identified by GWAS of leaf Pi content, while based on GWAS with novel hyperspectral indices revealed 78 candidate genes. Among these genes, six of them are known P responsive genes, two of which were predicted by both phenotypic inputs. Based on gene expression information, QTL mapping, and/or their potential functions from gene annotation, six candidate genes were proposed as novel genes involving in P-deficient response in rice, which can be validated and characterized in future studies.

CHULALONGKORN UNIVERSITY

Appendix A
Solution Formulas

A1. Yoshida's Solution (Stock Solution)

Stock code	Nutrient element	Chemical (AR grade)	g/liter
A	N	NH_4NO_3	91.400
B	P	$\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$	40.300
C	K	K_2SO_4	71.400
D	Ca	$\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$	117.372
E	Mg	$\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$	324.000
	Mn	$\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$	1.500
	Mo	$(\text{NH}_4)_6 \cdot \text{Mo}_7\text{O}_{24} \cdot 4\text{H}_2\text{O}$	0.074
F	B	H_3BO_3	0.934
	Zn	$\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$	0.035
	Cu	$\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$	0.031
G	Fe	Fe-EDTA	10.712
H	Na (instead of P deficient treatment)	NaCl	15.096

**A liter of working Yoshida's solution is prepared by using 1.25 ml of stock A-G.

For P deficient treatment, stock H is used instead of decreasing stock B in equal concentration to maintain comparable Na concentration.

A2. Molybdate Blue reagent

A solution

ammonium molybdate	4 g
0.5 M H ₂ SO ₄	1000 ml

B solution

ascorbic acid	10 g
distil water	100 ml

A and B solution are mixed together in 6:1 ratio, respectively, before use.

Appendix B

Supplementary results

Table B1 Leaf disc weight (mg/disc) of high and low Pi accumulators grown under different levels of P supply (320, 160, 80, 16, and 0.8 μM P). Data are means \pm SD (n = 3 samples; each sample was derived from an averaged pool of 80 leaf discs). Different letters indicate significant differences ($P < 0.05$), according to Duncan's multiple range test (DMRT).

Cultivar	P supply (μM)	Fresh weight of leaf disc (mg/disc)
High Pi accumulator	0.8	0.887 \pm 0.013 b
	16	1.025 \pm 0.003 a
	80	1.037 \pm 0.024 a
	160	1.036 \pm 0.028 a
	320	1.039 \pm 0.060 a
Low Pi accumulator	0.8	0.886 \pm 0.009 b
	16	1.022 \pm 0.022 a
	80	1.035 \pm 0.051 a
	160	1.035 \pm 0.025 a
	320	1.038 \pm 0.045 a

Table B2 Pi content ($\mu\text{mol}/\text{mm}^2$) from rice leaf grown under 320 (sufficient; S), 16 (mildly deficient; MD), and $0.8 \mu\text{M NaH}_2\text{PO}_4$ (severely deficient; SD). Data are means \pm SD (n = 9 samples).

Figure B1 Comparison of Pi contents determined by the punching method and total P contents determined by the ICP method. Data points are fitted by linear regression, and correlation (r) is determined by Pearson's correlation model using R software.

Figure B2 Full matrix correlation between NSR indices and Pi content.

Figure B3 Matrix correlation between its reflectance wavelength (A) and matrix correlation between NSR indices and Pi content (B) of randomly generated data.

Figure B4 Manhattan plot and Q-Q plot based on GWAS of Pi content measured from leaves grown under sufficient (A) and middle-deficient treatment (B). For Manhattan plots, the x-axis represents SNP positions across the entire rice genome by chromosome, and the y-axis is the $-\log_{10}$ p-value of each SNP.

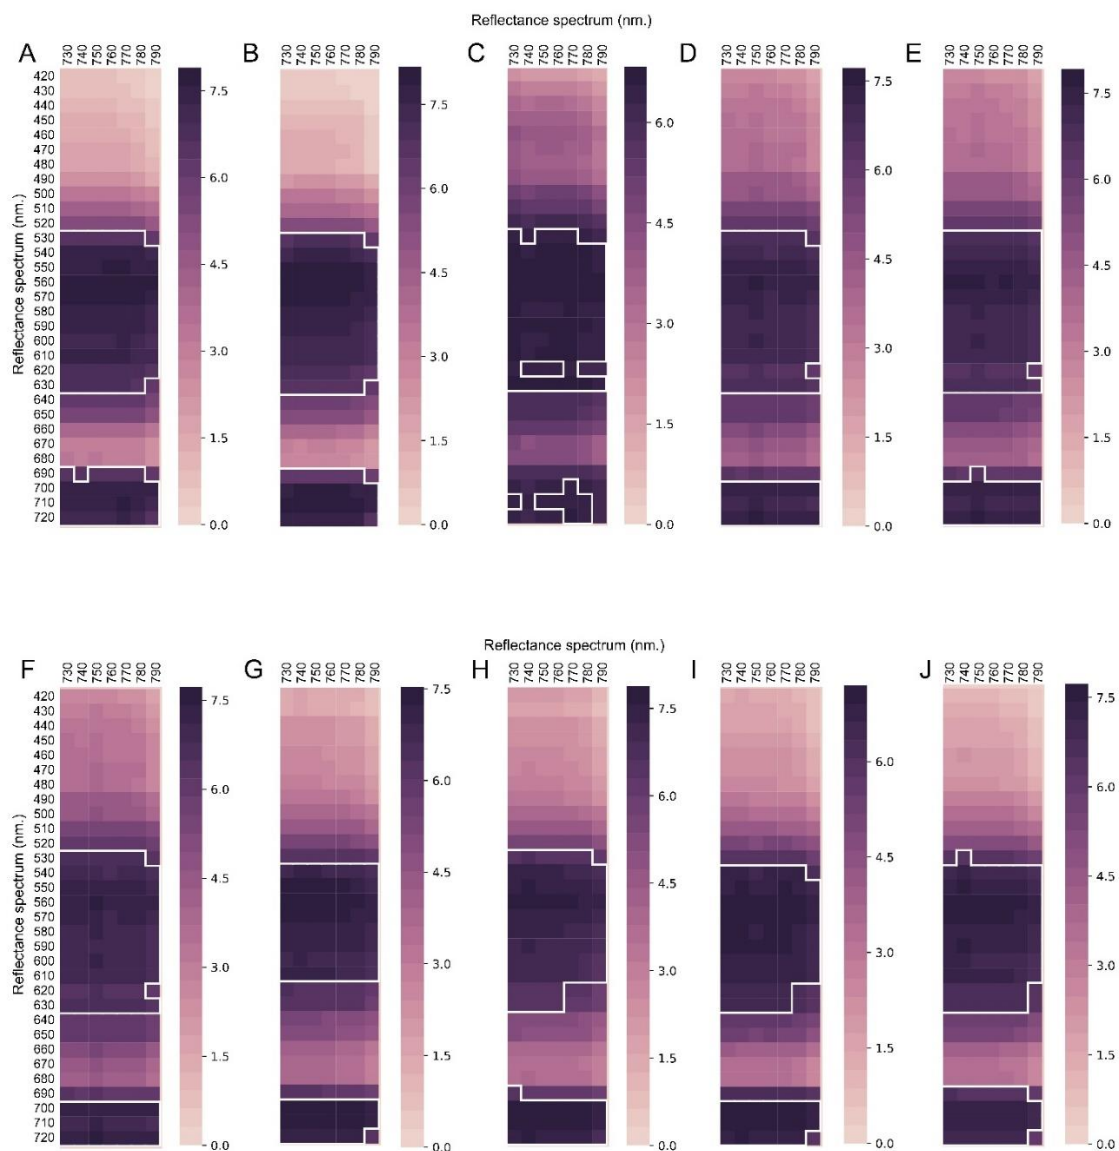

Figure B5 Heat map represents the significant SNPs located in ten candidate genes, including LOC_Os02g02670 (A), LOC_Os02g02690 (B), LOC_Os03g43730 (C), LOC_Os06g13650 (D), LOC_Os06g13670 (E), LOC_Os06g13680 (F), LOC_Os08g15230 (G), LOC_Os08g15330 (H), LOC_Os11g35320 (I), LOC_Os11g42300 (J). The surrounding white line indicated passed significant threshold line at $-\log(P\text{-value}) \geq 6.35$.

Appendix C

Detail of hyperspectral detective device and general vegetative indices

Table C1 Technical specification of PolyPen RP400 UVIS (PSI, 2018)

Spectrum measurement	
Spectral range	380 nm - 790 nm (RP 410 UVIS) 640 nm - 1050 nm (RP 410 NIR)
Spectral response half width	8 nm
Spectral Straylight	-30 dB
Scanning Speed	About 100 ms
Dynamic Range	High gain: 1:4300 Low gain: 1:13000
Size of Aperture	7 mm
Light source	
Type	Xenon incandescent lamp
Spectral range	380-1050 nm
Data storage and transfer	
Internal memory capacity	Up to 16 Mbit
Internal data logging	Up to 4,000 measurements
Data transfer	USB cable
PC software	SpectraPen 1.1 (Windows 7 and higher)
Battery	
Type	Li-Ion rechargeable battery
Capacity	2600 mAh
Max. charging current	0.5 A
Charging	Via USB port - PC, power bank, USB charger, etc.
Battery life	48 hours typical with full operation Low battery indicator
Other	
Sample holder	Mechanical leaf-clip
Display	Touchscreen 240 x 320 pixel; 65535 colors
Built in GPS module	Ultra-high sensitivity down to -165dBm High accuracy of <1.5 m in 50% of trials
Size	150 x 75 x 40 mm
Weight	300 g
Operating conditions	Temperature: 0 to +55 °C Relative humidity: 0 to 95 % (non-condensing)
Storage conditions	Temperature: -10 to +60 °C Relative humidity: 0 to 95 % (non-condensing)
Warranty	1 year parts and labor

Table C2 Detail of general vegetative spectral reflectance indices (PSI, 2018)

Spectral reflectance index	Abbreviation	Formula
Normalized Difference Vegetation Index	NDVI	$(R[780nm]-R[630nm]) / (R[780nm]+R[630nm])$
Simple Ratio Index	SR	$R[780nm]/R[630nm]$
Modified Chlorophyll Absorption Ratio Index 1	MCARI1	$1.2*(2.5*(R[780nm]-R[670nm])-1.3*(R[780nm]-R[550nm]))$
Optimized Soil-Adjusted Vegetation Index	OSAVI	$(1+0.16)*(R[780nm]-R[670nm]) / (R[780nm]+R[670nm]+0.16)$
Greenness Index	G	$R[554nm]/R[677nm]$
Modified Chlorophyll Absorption Ratio Index	MCARI	$((R[700nm]-R[670nm])-0.2*(R[700nm]-R[550nm]))* (R[700nm]/R[670nm])$
Transformed CAR Index	TCARI	$3*((R[700nm]-R[670nm])-0.2*(R[700nm]+R[550nm]))* (R[700nm]/R[670nm])$
Triangular Vegetation Index	TVI	$0.5*(120*(R[750nm]-R[550nm])-200*(R[670nm]-R[550nm]))$
Zarco-Tejada & Miller Index	ZMI	$R[750nm]/R[710nm]$
Simple Ratio Pigment Index	SPRI	$R[430nm]/R[680nm]$
Normalized Phaeophytinization Index	NPQI	$(R[415nm]-R[435nm]) / (R[415nm]+R[435nm])$
Photochemical Reflectance Index	PRI	$(R[531nm]-R[570nm]) / (R[531nm]+R[570nm])$
Normalized Pigment Chlorophyll Index	NPCI	$(R[680nm]-R[430nm]) / (R[680nm]+R[430nm])$
Carter Indices 1	Ctr1	$R[695nm]/R[420nm]$
Carter Indices 2	Ctr2	$R[695nm]/R[760nm]$
Lichtenthaler Indices 1	Lic1	$(R[780nm]-R[680nm]) / (R[780nm]+R[680nm])$
Lichtenthaler Indices 2	Lic2	$R[440nm]/R[690nm]$
Structure Intensive Pigment Index	SIPi	$(R[780nm]-R[450nm]) / (R[780nm]+R[650nm])$
Gitelson and Merzlyak Indices 1	GM1	$R[750nm]/R[550nm]$
Gitelson and Merzlyak Indices 2	GM2	$R[750nm]/R[700nm]$
Anthocyanin Reflectance Index 1	ARI1	$1/R[550nm]-1/R[700nm]$
Anthocyanin Reflectance Index 2	ARI2	$R[790nm]*(1/R[550nm]-1/R[700nm])$
Carotenoid Reflectance Index 1	CRI1	$1/R[510nm]-1/R[550nm]$
Carotenoid Reflectance Index 2	CRI2	$1/R[510nm]-1/R[700nm]$

Appendix D
Standard curve

Figure D1 Standard curve of Pi content (μM) for determining the leaf Pi content

Appendix E

Rice growing protocol

1. Seeds were sterilized using commercial bleach (2% sodium hypochlorite) for 10 minutes, then washed with distilled water three times, and continuously soaked the seeds in water for two days under dark condition.
2. Soaked seeds were floated on a plastic net in half-strength Yoshida solution for two days under dark condition.

3. Then the light was given to the seedling for four days.

Eight-day- old seedlings were pre-cultured for the next step

4. The seed endosperm was cut from the seedlings to remove the phosphorus storage resource, and the seedlings were transferred to full-strength Yoshida solution with different P concentrations for 16 days.

After 16 days, the treated rice can be harvested for any observation.

* This experiment was performed by using 80 L containers, which include 219 rice plants. The nutrient solution was renewed every four days and adjusted pH at 5.8 every two days.

จุฬาลงกรณ์มหาวิทยาลัย
CHULALONGKORN UNIVERSITY

VITA

NAME Sompop Pinit

DATE OF BIRTH 6 June 1991

PLACE OF BIRTH Phitsanulok

INSTITUTIONS ATTENDED Bachelor of Science in Biology (2nd Class Honor) from the Department of Biology, Faculty of Science, Naresuan University (2015)
Bachelor of Education major in Biology (1st Class Honor) from the Department of Education, Faculty of Education, Naresuan University (2015)

HOME ADDRESS 9/2, Village No.3, Noenkum, Bangkrathum, Phitsanulok, 65210 THAILAND

PUBLICATION Pinit, S., S. Chadchawan, and J. Chaiwanon. 2020. A simple high-throughput protocol for the extraction and quantification of inorganic phosphate in rice leaves. *Applications in Plant Sciences* 8(10): e11395.
DOI:10.1002/aps3.11395.

AWARD RECEIVED He was supported by the Royal Golden Jubilee Ph.D. Scholarship Grant (RGJ-Ph.D.) of Thailand Research Fund (TRF) to study for the degree of Doctor of Philosophy in Biotechnology Program, Faculty of Science, Chulalongkorn University.
