## CHAPTER IV

## RESULTS

## Cytochrome P450 2E1 (CYP2E1)

The present study investigated the correlation between the polymorphism of CYP2E1 gene and NPC on a total of 255 patients and 297 controls. PCR-RFLP analysis was used to evaluate RsaI polymorphism in the CYP2E1 (figure 7). The polymorphic of this gene had three type which were homozygous wild-type (+/+), heterozygous (+/-), and homologous variant ( $-/-$ ) forms. The homozygous wild-type form was digested both alleles with this enzyme. The fragments of wild-type form gave two bands at 360 and 50 bp, but the last band was absent due to its short fragment. The heterozygous form had both an uncut allele and a cut allele, so the fragments of this form gave three bands at 410, 360 and 50 bp . In the last type, homozygous variant form was not digested both alleles, and its fragment gave/a single undigested band at 410 bp . The distribution of alleles in all sample groups were found to be in Hardy-Weinberg equilibrium. The calculated frequencies of heterozygous using $2 \times(+/+)^{1 / 2} \times(-/-)^{1 / 2}$ were $0.32,0.26,0.42$ and 0.36 from Total, Thai, Chinese and Thai-Chinese NPC patients, and $0.31,0.26,0.42$ and 0.21 from Total, Thai, Chinese and Thai-Chinese controls, respectively. These numbers are similar to actual frequencies of heterozygous from all sample groups, 0.33, $0.28,0.41,0.41$ from Total, Thai, Chinese and Thai-Chinese patients, respectively and $0.35,0.28,0.52,0.24$ from Total, Thai, Chinese and Thai-Chinese controls, respectively. As show in Table 2, there was found the relative risk of the variant form (--) of the CYP2E1 at a high risk $[R R=2.10]$. However, this result had on statistical significance [95\% C $\left.C^{I}=0.90-4.96\right]$. To evaluate the relative risk from different genetic background both patients and controls were divided into three groups, Thai, Chinese, and ThaiChinese according to the origins of their ancestors. A slightly increasing in risk of the variant from $(-/-)$ of this gene could be demonstrated in Thai sample group $[R R=1.46$; $\left.95 \% C^{I}=0.23-11.63\right]$. Nevertheless, no statistically significance could be established. In the Chinese sample group, the variant homozygous alleles were at 2.22-fold increase
in risk of developing the disease but still without statistically significance $\left[95 \% C^{I}=\right.$ 0.78-6.41]. Interestingly in the Thai-Chinese sample group, the only one group had a higher $R R$ of heterozygous $(+/-)$ form $[R R=2.32]$. Additionally, its result had statistical significance $\left[95 \% C^{I}=1.17-4.61\right]$. The relative risk of variant form in this group could not be calculated because variant form in control group could not be observed. This study analyzed association of the pattern of genetic CYP2E1 and NPC phenotype by calculating the relative risk if the genotype was either Autosomal Dominant like (ADL) or Autosomal recessive like (ARL) form, contributing to phenotype by one or two alleles respectively. In ADL, the contribution of a single variant allele would show a higher RR. So that, the combination of the heterozygous ( $+/-$ ) and the variant form ( $(-)$ ) was computed for the RR when compare with wild-type (+/+). The association between ADL heredity and NPC risk could not be found in the total, Thai, and Chinese sample groups $\left[R R=1.00 ; 95 \% C^{I}=0.78-1.29, R R=1.01 ; 95 \% C^{I}=0.66-1.54, R R=0.81 ; 95 \% C^{I}=\right.$ $0.50-1.13$, respectively] but it could be found in the Thai-Chinese sample group $[R R=$ 2.53; $95 \% C^{I}=1.29-4.97$ ] (Table 3). However, these results shown no statistical significance in almost sample groups exceptionally in Thai-Chinese sample group. In contrast, ARL concerns the abnormality in both alleles of CYP2E1. The RR were calculated by comparison between the wild type $(+/+)$, the heterozygous ( $+/$ ) or the combination of the wild type and heterozygous ( $+/+$ and $+/-$ ) and the variant form ( $(-)$ ). The higher RR value in all comparison was concerned ARL pattern in all sample groups (Table 4). These results of ARL pattern had no statistical significance as same as ADL pattern. Exceptionally, the result of Chinese sample group when heterozygous ( $+/$ ) form compare with variant ( - - ) form had statistical significance $\left[\mathrm{RR}=3.19 ; 95 \% \mathrm{C}^{\mathrm{I}}=1.12\right.$ 9.23, respectively]. In conclusion, all case-control data from all groups suggest the role of the mutation of this gene on NPC development as in Taiwan. The insignificant RR value from some categories should be due to lower number of samples

## Complement receptor type 2 (CR2)

A previous study reported the TaqI sites of CR2 near the exon1,2 by using the pBCR2-12.1 as DNA probe for Southern blotting and hybridization. ${ }^{93}$ In order to locate this site, a primer set, ranged from exon 1,2 to exon4b, were used for the PCR assay. Digestion of the 2.6 kb PCR product with TaqI produced fragments at $1.7 \mathrm{~kb}, 617 \mathrm{bp}$ and 300bp. The 1.7 kb fragment was either present or absent. In otherword, the polymorphic TaqI should locate at 1.7 kb fragment, which may be at CR2 intron2 or 3 . Accordingly, the second primer set was designed to proved the location, shorten PCR product and for improve efficiency in RFLP reading at intron2 region (Figure 8). On digestion with TaqI, there is a single undigested band at 1241 bp in homozygous wild-type (---) form and are digested products at 750 and 491 bp in homozygous variant (+/+) form. In heterozygous ( $+/-$ ) form, the fragments gave three bands at 1241, 750, and 491 bp (Figure 9). The distribution of alleles in all sample groups were found to be in HardyWeinberg equilibrium. The calculated frequencies of heterozygous using $2 \times(+/+)^{1 / 2} \times(-/-$ $)^{1 / 2}$ were $0.23,0.24,0.20$ and 0.30 from Total, Thai, Chinese and Thai-Chinese NPC patients, and $0.20,0.21,0.20$ and 0.20 from Total, Thai, Chinese and Thai-Chinese controls, respectively. These numbers are similar to actual frequencies of heterozygous from all sample groups, $0.24,0.28,0.18,0.28$ from Total, Thai, Chinese and ThaiChinese patients, respectively and $0.21,0.22,0.20,0.22$ from Total, Thai, Chinese and Thai-Chinese controls, respectively. As shown in table5, a slightly increasing in risk but without statistically significant of heterozygous (+/-) and variant (+/+) form of the CR2 could be demonstrated in all sample groups. In Chinese samples group, only one group was not found the association between heterozygous ( $+/-$ ) and NPC risk $[R R=0.94$; $\left.95 \% \mathrm{C}^{\mathrm{I}}=0.47-1.80\right]$. Furthermore, we evaluated whether there is any correlation between CR2 mode of inheritances and NPC phenotype. There was slight increase in NPC RR if CR2 was calculated via ADL in total, Thai and Thai-Chinese sample groups $\left[R R=1.21 ; 95 \% C^{I}=0.90-1.63, R R=1.34 ; 95 \% C^{I}=0.85-2.13, R R=1.67 ; 95 \% C^{I}=\right.$ $0.78-3.43$, respectively] but not in the Chinese sample group $\left[\mathrm{RR}=0.99 ; 95 \% \mathrm{C}^{\mathrm{I}}=\right.$ $0.51-1.86]$ (Table 6). In ARL heredity, the slight higher RR value was found in only two
groups, total sample group $[R R=1.33 ; 95 \% \mathrm{CI}=0.25-7.20, \mathrm{RR}=1.11 ; 95 \% \mathrm{CI}=$ $0.20-6.07, \mathrm{RR}=1.28 ; 95 \% \mathrm{CI}=0.24-6.89]$ and Chinese sample group $[\mathrm{RR}=1.98$; $95 \% \mathrm{CI}=0.14-27.39, \mathrm{RR}=2.11 ; 95 \% \mathrm{CI}=0.14-29.75, \mathrm{RR}=2.00 ; 95 \% \mathrm{CI}=0.14-$ 27.71] (Table7). However, all results of this gene had no statistical significance. In conclusion, our study indicates no association between CR2 genotype and NPC phenotype. This suggests that CR2 is not likely a susceptible gene for NPC development.

## Polymeric immunoglobulin receptor (pIgR)

Identification of polymorphic pIgR gene was analyzed with PvuII nuclease in altogether 224 cases and 296 controls. In a previous study, Southern blot analysis of PvuII-digested genomic DNA hybridized with the 0.67 kb PvuII cDNA probe, indicating the presence of the polymorphic cleavage site located in intron $3 .{ }^{93}$ Hence, in this study, the PCR products of this gene were confirmed that the cleavage sites of this enzyme located in intron3 by using designed new primers (Figure 10). As shown in the figure 11, the fragments of homozygous wild-type ( $+/+$ ) form gave bands of digestion products at 1163 and 229 bp and homozygous variant (--) form gave only a single undigested band at 1392 bp . Heterozygous (+/-) form had all three bands. The distribution of alleles in all sample groups were found to be in Hardy-Weinberg equilibrium. The calculated frequencies of heterozygous using $2 x(+/+)^{1 / 2} \times(-/-)^{1 / 2}$ were $0.49,0.49,0.50$ and 0.48 from Total, Thai, Chinese and Thai-Chinese NPC patients, and $0.48,0.49,0.48$ and 0.47 from Total, Thai, Chinese and Thai-Chinese controls, respectively. These numbers are similar to actual frequencies of heterozygous from all sample groups, $0.55,0.55,0.58,0.56$ from Total, Thai, Chinese and Thai-Chinese patients, respectively and $0.50,0.59,0.44,0.48$ from Total, Thai, Chinese and ThaiChinese controls, respectively. The result showed association between plgR gene and NPC development (Table8). The Chinese sample group not only had a higher RR value but also statistical significance of both heterozygous ( $+/-$ ) form and variant ( $-/$ ) form [RR $=2.77 ; 95 \% \mathrm{C}^{\mathrm{I}}=1.63-4.73, \mathrm{RR}=2.90 ; 95 \% \mathrm{C}^{\mathrm{I}}=1.30-6.39$, respectively]. Including, the result of heterozygous (+/-) form from total sample group was also statistical significance but the $R R$ value was lower than Chinese sample group $\left[R R=1.37 ; 95 \% C^{I}\right.$ $=1.03-1.83]$. The relative risk of Thai and Thai-Chinese sample group had a slightly increasing risk and not statistical significance. Interestingly, the higher RR value was concerned ADL heredity in Chinese sample group $\left[R R=2.81 ; 95 \% \mathrm{C}^{\mathrm{I}}=1.52-5.34\right]$ as the same result in total sample group $\left[R R=1.38 ; 95 \% C^{I}=1.05-1.82\right]$ (Table9). ThaiChinese sample group showed also result but not statistical significance $[R R=1.36$; $\left.95 \% \mathrm{C}^{\mathrm{I}}=0.68-2.81\right]$. Exceptionally, Thai sample group was not found risk of NPC
development $[R R=0.91 ; 95 \% \mathrm{CI}=0.59-1.40]$. Interestingly, ARL pattern of this gene was not agreed since there is no distinction between heterozygous and homozygous variant (Table10). This data suggests that the pIgR RFLP may link to an ancient functional variant allele, especially from Chinese population and having heterozygous or homozygous of this allele can contribute to NPC susceptibility.
