อำนวยการ

กระบวนการไฟฟ้าเคมีทางแสงสำหรับปฏิกิริยารีดักชัน CO<sub>2</sub> (CO<sub>2</sub> reduction reaction: CO<sub>2</sub> RR) เป็นหนึ่งในวิธีที่สามารถนำ CO<sub>2</sub> นำไปใช้ประโยชน์ คาร์บอนมอนอกไซด์ (CO) และฟอร์มเมตไอออน (HCOO<sup>-</sup>) เป็นผลิตภัณฑ์ที่น่าสนใจ ที่ได้จาก CO<sub>2</sub> RR ดังนั้นขนาดรูปแบบและจัดเรียงตัวส่วนประกอบของ PEC cell จึงมีบทบาทสำคัญที่ส่งผลต่อประสิทธิภาพของเซลล์และผลผลิตที่ได้จาก CO<sub>2</sub> RR ในงานนี้ ความสัมพันธ์ของอุทกพลศาสตร์ของของไหลและจลนพลศาสตร์ของประจุระหว่างขั้วโฟโตอิเล็กโทรดทางฝั่งแอโนดที่ใช้ TiO<sub>2</sub> เป็นสารกึ่งตัวนำ และขั้วแคโทดใช้อิเล็กโทรดทางฝั่งแคโทดที่ใช้ SnO<sub>2</sub> เคลือบบนขั้วที่มีชั้นสำหรับแพร่ก๊าซ (Gas diffusion electrode: GDE) ถูกนำมาศึกษาโดยใช้ COMSOL Multiphysics (5.6) สำหรับเซลล์ไฟฟ้าเคมีทางแสงที่มีรูปแบบการจัดเรียงส่วนประกอบที่แตกต่างกัน ภายใต้สภาวะการทำงานเดียวกัน เซลล์ไฟฟ้าเคมีทางแสงที่มีรูปแบบ Microfluidic flow cell (MFC) with a zero-gap anode ที่ใช้ค่าสัมบูรณ์ศักย์ไฟฟ้าของเซลล์ 1.5 V และค่าหนาแน่นกระแส 10 A•m<sup>-2</sup> ที่ขั้วโฟโตอิเล็กโทรด ได้ค่าการเลือกเกิดของผลิตภัณฑ์ของHCOO<sup>-</sup> เท่ากับ 0.62 ประสิทธิภาพแบบฟาราเดย์ของHCOO<sup>-</sup> ร้อยละ 68.6 และประสิทธิภาพทางพลังงานของHCOO<sup>-</sup> ร้อยละ 60.4 ดังนั้น MFC with a zero-gap anode เป็นตัวเลือกโมเดลที่ดีที่สุดสำหรับการผลิต เนื่องจากสามารถแก้ไขข้อจำกัดการถ่ายโอนมวลสารและการสูญเสียโอห์มมิก จากการควมครี้งเซลล์ของรูปแบบ MFC และ Membrane electrode assembly flow cell (MEAFC) นอกจากนี้ผลจากการจำลองยังแสดงว่าที่ ความหนาแน่นกระแส 1.0 mA•cm<sup>-2</sup> ความยาวเซลล์ (L<sub>cell</sub>) 1.5 cm ความกว้างของช่องก๊าซ (W<sub>g</sub>) 1.5 mm และความกว้างของช่องอิเล็กโทรไลต์ (W<sub>l</sub>) 2.0 mm เป็นค่าที่เหมาะสมสำหรับระบบนี้

KEYWORD: CO<sub>2</sub> reduction, Photoelectrochemical cell, GDE, Formate production,  
COMSOL

Aaronroj Chaosukho : Simulation of Photoelectrochemical CO<sub>2</sub> Conversion  
to Useful Chemicals. Advisor: Asst. Prof. Paravee Vas-Umnuay, Ph.D.

Photoelectrochemical (PEC) CO<sub>2</sub> reduction reaction (CO<sub>2</sub> RR) is one of the possible solutions to reduce CO<sub>2</sub> emissions. Among a variety of products derived from CO<sub>2</sub> RR, CO, and HCOO<sup>-</sup> are found to be interesting chemicals. The geometry and arrangement of the main components of PEC cells play important roles in the cell performance of CO<sub>2</sub> RR. In this study, a correlation of hydrodynamics and kinetics on the TiO<sub>2</sub>-photoanode and SnO<sub>2</sub>-GDE, used as a cathode, was investigated by COMSOL Multiphysics by controlling operating conditions for 2-dimensional different PEC cell configurations. The Microfluidic flow cell (MFC) with a zero-gap anode with a zero-gap anode provided selectivity of 0.62 HCOO<sup>-</sup>, faradaic efficiency of 68.6% HCOO<sup>-</sup>, and energy efficiency of 60.4% HCOO<sup>-</sup> which were achieved with applied absolute cell voltage at 1.5 V and 1.0 mA•cm<sup>-2</sup> photocurrent density on the TiO<sub>2</sub> photoanode. Therefore, MFC with a zero-gap anode was chosen as the optimal design overcoming the limitation of mass transfer and ohmic overpotential loss by integrating half-cells of the MFC and membrane electrode assembly flow cell (MEAFC) configurations. Moreover, the results showed 1.0 mA•cm<sup>-2</sup> of current density, 1.5 cm of cell length ( $L_{\text{cell}}$ ), 1.5 mm of gas channel width ( $W_g$ ), and 2.0 mm of electrolyte channel width ( $W_l$ ) which were the optimum values for this system.

## ACKNOWLEDGEMENTS

Firstly, I would like to express my sincere gratitude and appreciation to my research advisor, Assistant Professor Paravee Vas-Umnuay, Ph.D., Department of Chemical Engineering, Chulalongkorn University, to provide me with the opportunities, guidance, and inspired experiment to undertake excellent research.

Moreover, I would also like to extend my thanks to the thesis committee members, Associate Professor Soorathep Kheawhom, Assistant Professor Palang Bumroongsakulsawat, and Assistant Professor Weekit Sirisaksoontorn, for imparting useful suggestions, encouragement, and participation as thesis committee.

Finally, my thesis could not have been accomplished without the support everything from my love family who have motivated me to achieve my degree as well as the member of the Center of Excellence in Particle Technology in Chulalongkorn University - thank you for their friendship and positivity. This absolutely would not have happened without them.

Aroonroj Chaosukho

## Chapter 1

### INTRODUCTION

#### 1.1 Background

Global climate change leads to the rise in global temperature caused by the greenhouse effect. The greenhouse effect occurs when greenhouse gases are growing and these gases in the earth's atmosphere trap the sun's heat. Greenhouse gases (GHGs) consist of water vapor, carbon dioxide ( $\text{CO}_2$ ), methane ( $\text{CH}_4$ ), nitrous oxide ( $\text{N}_2\text{O}$ ), hydrofluorocarbons (HFCs), perfluorocarbons (PECs), and sulfur hexafluorides ( $\text{SF}_6$ ), respectively.  $\text{CO}_2$  is counted as the major concentration of greenhouse gases out of water vapor [1].  $\text{CO}_2$  is emitted from many sources such as fossil fuel combustion for energy conversion and transportation, industrial processes, and land-use change. In the 2010s, the world emitted  $\text{CO}_2$  from fuels over 35.13 billion tones each year and now emits over 34 billion tones each year [2]. In addition, the higher dissociation energy for breaking the C=O bond supports the stability of  $\text{CO}_2$  molecules, therefore, resulting in the complexity of  $\text{CO}_2$  reduction. Chemical products from the  $\text{CO}_2$  reduction reaction ( $\text{CO}_2$  RR) can be used in various chemical industries and developed into many useful products. Carbon monoxide (CO) and formate ion ( $\text{HCOO}^-$ ) can be used in a wide range of applications, for example, CO is used in the Fisher-Tropsch process to produce liquid hydrocarbons, and  $\text{HCOO}^-$  is used as a material in dyeing and tanning industries. CO and  $\text{HCOO}^-$  are interesting and useful chemicals from  $\text{CO}_2$  RR due to their value growth and market size [3, 4]. To completely overcome the difficult challenge for  $\text{CO}_2$  RR, various alternative methods consist of thermochemical, biochemical, electrochemical, photochemical, and photoelectrochemical (PEC) processes. Among these, the PEC process has been used to solve the difficult challenge for  $\text{CO}_2$  RR due to the advantages in energy consumption and operating under ambient conditions through the integration of renewable solar energy and external electric field [5].

However, the efficiency of PEC CO<sub>2</sub>RR should be concerned for PEC cells design through many effects such as light intensity, operating mode (batch system and continuous flow system), operating conditions (temperature, pressure, flow rate, and cell voltage), bandgap (type of semiconductors), pH (type of electrolyte), product separator (type of ion-exchange membrane), and cell configurations. The PEC cell configurations refer to the main components consisting of photoelectrode, counter-electrode, electrolyte, and product membrane. The geometric configuration and arrangement of these components have been simulated to observe the performance and productivity of CO<sub>2</sub>RR [6, 7]. B. Endrodi et al. [8] showed zero-gap membrane electrolyzer cells for CO<sub>2</sub> RR through a multilayer CO<sub>2</sub> electrolyzer stack. The electrolyzer cell was an arrangement of gas diffusion electrode (GDE), anode catalyst layer (ACL), bipolar plate (BPP), and an anion exchange membrane (AEM) in sequence. The pressurized CO<sub>2</sub> gas feed and GDEs were applied in a continuous flow electrolyzer to solve the low solubility of CO<sub>2</sub> and offer a high surface area for CO<sub>2</sub> RR. Therefore, direct-fed CO<sub>2</sub> gas in parallel to a multilayer electrolyzer stack could improve about 95% faradaic efficiency (FE) of CO formation in which a partial current density of CO could be up to 300 mA cm<sup>-2</sup>. In addition, the efficiency of CO<sub>2</sub> conversion was increased up to 40% when the arrangement of multilayer CO<sub>2</sub> electrolyzer stacked in the series direction due to off-gas (remnant CO<sub>2</sub> reactant) was continued flow to sequence layers.

To demonstrate the performance and productivity of CO<sub>2</sub> RR, through the PEC cells, the PEC cells were designed and arranged in different configurations namely 1) microfluidic flow cell (MFC), 2) membrane electrode assembly flow cell (MEAFC), and 3) microfluidic flow cell (MFC) with a zero-gap anode. These configurations were simulated under identical operating conditions. Besides, the optimum geometric configurations of the main components were also identified through simulation. The results are shown through CO<sub>2</sub> conversion, selectivity,

faradaic efficiency (FE), and the energy efficiency (EE) of products as the performance indicators of the PEC process of CO<sub>2</sub>RR.

## 1.2 Objectives

1. To study computational modeling of the PEC process of CO<sub>2</sub> RR to produce CO and HCOO<sup>-</sup> using COMSOL Multiphysics (5.6).
2. To investigate and compare the effects of different configurations of PEC cells through behaviors of CO<sub>2</sub> conversion, selectivity, faradaic efficiency, and the energy efficiency of CO<sub>2</sub> RR to CO and HCOO<sup>-</sup> when operating under identical conditions.

## 1.3 Scopes of research

COMSOL Multiphysics (5.6) was used to model and simulate the PEC process for CO<sub>2</sub> RR to CO and HCOO<sup>-</sup>. The model was assumed to be operated at a steady-state condition. Both gas and liquid feeds were treated as ideal and incompressible fluids transported through diffusion and convection. In addition, the model was validated with a system that has similar conditions through the previous research papers.

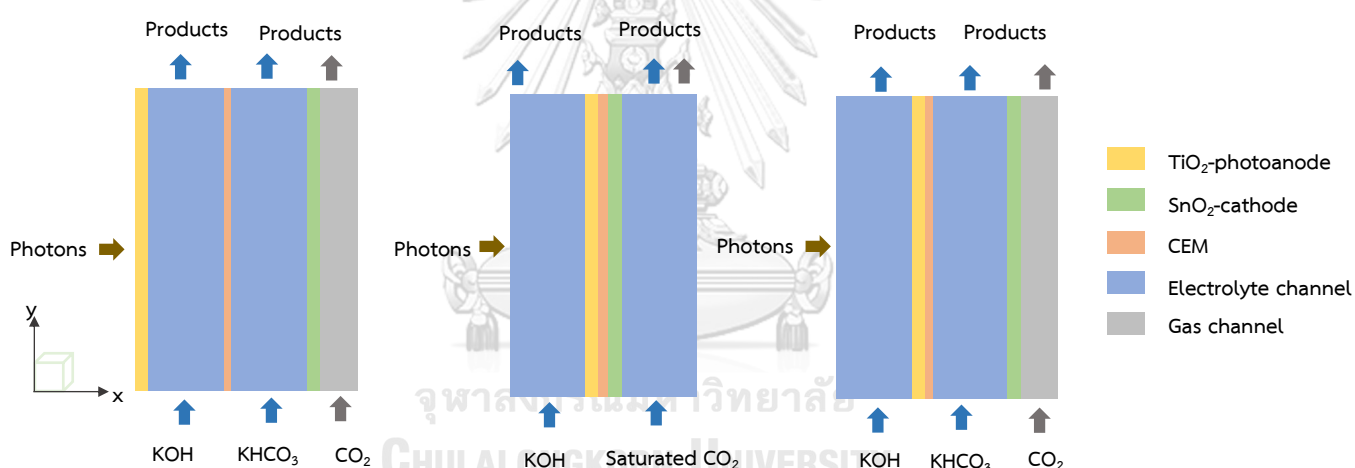

### 1.3.1 Controlled variables

The main components were specified for PEC CO<sub>2</sub> RR to obtain selected products under ambient operating conditions, and GDEs were applied for two electrodes. The n-type semiconductor or titanium dioxide (TiO<sub>2</sub>) was used as a photocatalyst for back-illumination of the photoanode compartment while tin (IV) oxide (SnO<sub>2</sub>) was used as an electrocatalyst for CO<sub>2</sub> RR of the cathode compartment, respectively. The Nafion-117 was used as a proton exchange membrane (PEM) to separate the PEC cell and transfer protons (H<sup>+</sup>) from the anodic to the cathodic compartment. The anolyte and catholyte channels were fed with potassium hydroxide (KOH) and potassium bicarbonate (KHCO<sub>3</sub>) under a controlled concentration and flow rate to sustain the pH of the system. The supplied energy for

CO<sub>2</sub> RR was controlled through applied photocurrent density to overcome the thermodynamics of CO<sub>2</sub> RR.

### 1.3.2 The 2-dimensional model of PEC cell configurations

The main components with the specific thickness of the PCE cell were arranged in the x-direction with different positions. The 2-dimensional model of the PEC cell was operated under a continuous flow of reactants and electrolytes that entered from bottom to top in the y-direction in laminar flow. The description of different configurations of PCE cells are designed namely as follows: 1) microfluidic flow cell (MFC), 2) membrane electrode assembly flow cell (MEAFC), and 3) microfluidic flow cell (MFC) with a zero-gap anode as shown in figure 1.

**Figure 1.** Diagram of different PEC cell for CO<sub>2</sub> RR.

#### 1. Microfluidic flow cell (MFC)

The 6 domains of MFC were assembled from left to right side in x-direction including TiO<sub>2</sub>-photoanode, anolyte channel, PEM, catholyte channel, SnO<sub>2</sub>-cathode, and gas channel, respectively. CO<sub>2</sub> in the gas phase was fed to SnO<sub>2</sub>-cathode through the gas feed channel while KOH and KHCO<sub>3</sub> were fed in the anolyte and catholyte channels, respectively. The compartment between the anode and the cathode was inserted using PEM to prevent the crossing over of the products in PEC cells.

## 2. Membrane electrode assembly flow cell (MEAFC)

The 5 domains of MEAFC were assembled from left to right side in x-direction including the anolyte channel, TiO<sub>2</sub>-photoanode, membrane, SnO<sub>2</sub>-cathode, and catholyte channel respectively. Saturated CO<sub>2</sub> and KHCO<sub>3</sub> were fed to the catholyte channel while KOH was fed to the anolyte channel. The compartment between the anode and the cathode was inserted using PEM to prevent the crossing over of the products in PEC cells.

## 3. Microfluidic flow cell (MFC) a zero-gap anode

The 6 domains of MFC with a zero-gap anode were assembled from left to right side in x-direction including the anolyte channel, TiO<sub>2</sub>-photoanode, membrane, catholyte channel, SnO<sub>2</sub>-cathode, and gas channel, respectively. CO<sub>2</sub> in the gas phase was fed to SnO<sub>2</sub>-cathode through the gas feed channel while KOH and KHCO<sub>3</sub> were fed in the anolyte and catholyte channels, respectively. The compartment between the anode and the cathode was inserted using PEM to prevent the crossing over of the products in PEC cells.

### 1.3.3 Performance indicators

#### 1. CO<sub>2</sub> conversion ( $X_{CO_2}$ )

CO<sub>2</sub> conversion is defined as a ratio of the amount of CO<sub>2</sub> reactant that can be reacted to chemical products to the amount of CO<sub>2</sub> reactant.

#### 2. Selectivity ( $S$ )

Selectivity is the number of moles of interested product formed per the number of moles of overall products formed.

#### 3. Faradaic efficiency (FE)

FE represents the amount of fuel consumption with the amount of obtained current. The FE for PEC CO<sub>2</sub> reduction can be defined as a ratio of the current that promotes CO<sub>2</sub> conversion into chemical fuels to the received current.

#### 4. Energy efficiency (EE)

EE is the amount of the electric energy that is supplied to the cell for interested product formation.

##### 1.3.4 Variables affecting PEC cell for CO<sub>2</sub> RR

In order to study variables affecting system efficiency, the physics models in the simulation were used to evaluate the variation of the factors that affecting PEC cell for CO<sub>2</sub> RR.

#### 1. Physics model validation

To validate the accuracy of physics model for simulation, the correlation of FE and absolute cell voltage curve which absolute cell voltage was varied between 1.5 – 3.5 V.

#### 2. Arrangement of PEC cell configuration

To evaluate the effect of arrangement of PEC cell on cell performance, the different PEC cell configurations consist of MFC, MEAFC, and MFC with a zero-gap anode were simulated under specific controlled variables.

#### 3. Light intensity

To evaluate the effect of energy consumption on cell performance, light intensity ( $\text{mW}\cdot\text{cm}^{-2}$ ) was applied in a form of photocurrent density of 0.1, 0.5, 1.0, 5.0, 10.0, and 15.0  $\text{mA}\cdot\text{cm}^{-2}$  with specific boundary electric potential initial value.

#### 4. PCE cell length

To evaluate the effect of surface area of PEC cell on cell performance, PEC cell lengths of 1.0, 1.5, 3.0, 4.0, 6.0, 8.0, and 10.0 cm were varied with specific controlled PEC cell height.

#### 5. Gas channel width

To evaluate the effect of geometric configuration of PEC cell on cell performance, gas channel widths of 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0 and 8.0 mm were varied with specific controlled surface area of PEC cell.

#### 6. Electrolyte channel width

To evaluate the effect of geometric configuration of PEC cell on cell performance, electrolyte channel widths of 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0 and 8.0 mm were varied with specific controlled surface area of PEC cell.

### 1.4 Expect outputs

1. Apply conservative equation and kinetics expression of the PEC process for  $\text{CO}_2$  RR to CO and  $\text{HCOO}^-$  in computational modeling through COMSOL Multiphysics (5.6).
2. Evaluate domination of each PEC cell configuration by using  $\text{CO}_2$  conversion, selectivity, faradaic efficiency, and energy efficiency behaviors from the PEC process of  $\text{CO}_2$  RR to CO and  $\text{HCOO}^-$ .
3. Apply optimum PEC cell configuration for scaling up in  $\text{CO}_2$  conversion industries.

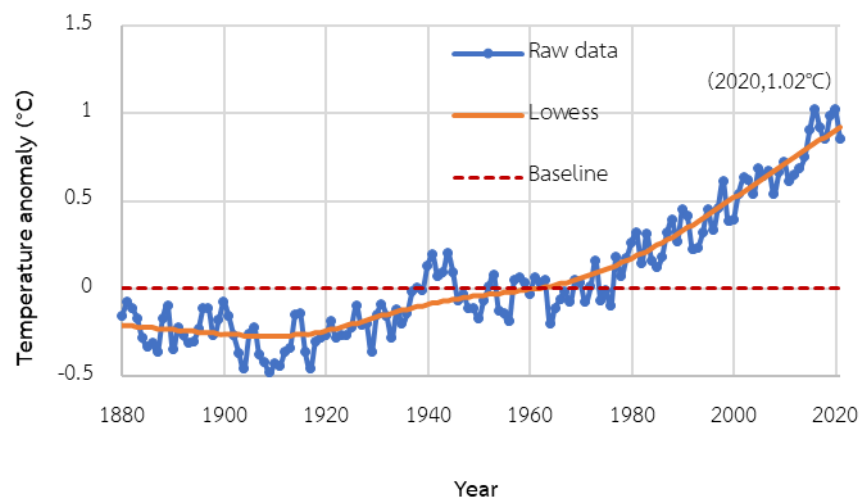

## Chapter 2

### THEORETICAL BACKGROUND AND LITERATURE REVIEW

#### 2.1 Global climate change and greenhouse gases

Global climate change can be measured from the climate over a long period which results from an increase in greenhouse gases in the atmosphere. Global climate change and greenhouse gases are the important data that should be concerned.

##### 2.1.1 Global climate change

**Figure 2.** The annual global temperature anomaly (°C) [9].

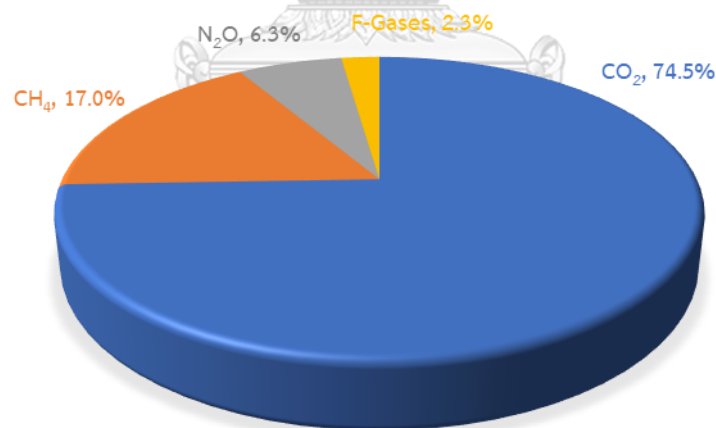

Global climate change refers to a weather variation in the long-term initiated by the greenhouse effect and the increase of greenhouse gases (GHGs). The effect of global climate change can lead to many phenomena, in which the different forms of warning signs had been occurring such as higher sea levels, algal blooms, wildfire, and air pollution [10].

From figure 2, the NASA Goddard Institute for Space Studies (GISS) collected global temperature to perform a model of surface temperature analysis (GISTEMP v4) and estimated annual global surface temperature anomalies, in which the optimum baseline period of temperature from 1951 to 1980 is fixed, referred from NASA's analysis. The global surface temperature variation was plotted through raw data and

locally weighted scatterplot smoothing (Lowess) data to observe the trend of temperature anomaly. In 2016 and 2020, maximum temperature anomalies could increase to 1 degree celsius, which was the highest record since the industrial revolution in 1980. Moreover, the trend of global temperature anomaly is still increasing at present [9].

### 2.1.2 Greenhouse gases

The GHGs are gases existing in the atmosphere that can trap and emit heat in the infrared range. Although the optimum existence of GHGs promotes warming on the earth's surface to maintain temperature and prevent our life from dangerous solar radiation, excess concentration of GHGs causes an important role in global climate change. The major GHGs include water vapor, carbon dioxide ( $\text{CO}_2$ ), methane ( $\text{CH}_4$ ), nitrous oxides ( $\text{NO}_x$ ), hydrofluorocarbons (HFCs), perfluorocarbons (PECs), and sulfur hexafluoride ( $\text{SF}_6$ ) [11].

**Figure 3.** World greenhouse gas emission in 2018 [12].

From figure 3, the total GHGs emission in 2018 was estimated at 48.9 Gt  $\text{CO}_2\text{eq}$  which emission of each gas can be represented by using  $\text{CO}_2\text{eq}$  or carbon dioxide equivalents multiply by its 100-year global warming potential (GWP) value. Among the GHGs, the amount of  $\text{CO}_2$  emission is around 36.4 Gt  $\text{CO}_2\text{eq}$  or 74.5% of GHGs emissions [13].

## 2.2 CO<sub>2</sub>

Due to CO<sub>2</sub> being the major gas of GHGs that is causing global warming, CO<sub>2</sub> emission also relates to the concentration GHGs in the atmosphere. Therefore, the properties of CO<sub>2</sub> are studied to define the optimum strategies for CO<sub>2</sub> reduction.

### 2.2.1 CO<sub>2</sub> Emission

In 2020, the trend of the amount of global CO<sub>2</sub> emission from fuels decreased because the COVID-19 pandemic has impacted global economic activities. However, the overall trend of global CO<sub>2</sub> emission from fuels has increased, reaching 34 billion tons per year as shown in figure 4 [2].

Figure 4. Global CO<sub>2</sub> emission from fossil fuels [2].

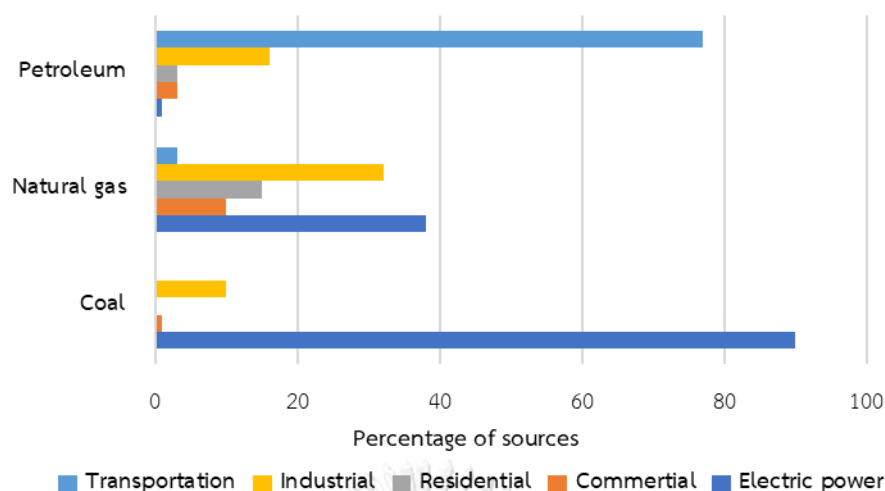

Figure 5. U.S. energy-related CO<sub>2</sub> emissions by source in 2020 [14].

**Figure 6.** U.S. CO<sub>2</sub> emissions from energy consumption by source and sector in 2020 [15].

The U.S. energy information administration [14] shows the total amount of total annual U.S. energy-related CO<sub>2</sub> emission in 2020 was 4,571 million metric tons. The primary source of CO<sub>2</sub> emissions could be obtained from fossil fuel combustion derived from petroleum, natural gas, and coal. The fraction of fossil fuel as shown in figure 5.

Moreover, figure 6 presents the fraction of end-use sectors provided by fossil fuel combustion including non-electric power and electric power sectors. Non-electric power was used in many human activities consisting of transportation, industrial, residential, and commercial [15].

### 2.2.2 Properties of CO<sub>2</sub>

Carbon dioxide (CO<sub>2</sub>) is a chemical compound that covalent bonding of two atoms of oxygen with one atom of carbon. The stability of CO<sub>2</sub> molecules is presented because double bonds of compound (O=C=O) provide symmetric structure and 8 valence electrons of carbon follow Octet's rule. The dissociation energy for breaking the C=O bond (~750 kJ mol<sup>-1</sup>) is higher than other chemical bonding such as the C-H bond (~430 kJ mol<sup>-1</sup>) and the C-C bond (~336 kJ mol<sup>-1</sup>) resulting in high energy consumption is required. In addition, CO<sub>2</sub> is a gas at normal

temperature and pressure due to the nonpolar properties of molecules. Therefore, high barriers of properties and low solubility of CO<sub>2</sub> can inherent CO<sub>2</sub> conversion to value-added products [4, 16].

The chemical products derived from the highest chemical state (+4) of carbon atom in CO<sub>2</sub> reduction such as carbon monoxide (CO), formic acid (HCOOH), formaldehyde (CH<sub>2</sub>O), methanol (CH<sub>3</sub>OH), and methane (CH<sub>4</sub>) indicate the higher positive value of ΔG° when compared with water splitting reaction which is shown in table 1.

**Table 1.** Some of the possible thermodynamic reactions of CO<sub>2</sub> reduction, the standard enthalpy (ΔH°), Gibbs free energy (ΔG°), and redox potential (E°) [4, 5].

Reaction	ΔH° (kJ mol <sup>-1</sup> )	ΔG (kJ mol <sup>-1</sup> )	ΔE° (V)
H <sub>2</sub> O(l) → H <sub>2</sub> (g) + 1/2O <sub>2</sub> (g)	286	237	1.23
CO <sub>2</sub> (g) → CO(g) + 1/2 O <sub>2</sub> (g)	283	257	1.33
CO <sub>2</sub> (g) + H <sub>2</sub> O(l) → HCOOH(l) + 1/2O <sub>2</sub> (g)	270	286	1.48
CO <sub>2</sub> (g) + H <sub>2</sub> O(l) → CH <sub>2</sub> O(l) + O <sub>2</sub> (g)	563	522	1.35
CO <sub>2</sub> (g) + 2H <sub>2</sub> O(l) → CH <sub>3</sub> OH(l) + 3/2O <sub>2</sub> (g)	727	703	1.21
CO <sub>2</sub> (g) + 2H <sub>2</sub> O(l) → CH <sub>4</sub> (g) + 2O <sub>2</sub> (g)	890	818	1.06

The relation between standard Gibbs free energy change (ΔG°) and the standard cell potential (ΔE°) of reduction reaction can be identified by using Eq. (1) [4].

$$\Delta E^\circ = -\frac{\Delta G^\circ}{nF} \quad \text{Eq. (1)}$$

where ΔE° is the standard cell potential derived from the difference of standard potential between two (ΔE° = E<sub>1</sub>° - E<sub>2</sub>°) (V)

ΔG° is the standard Gibbs free energy change

n is the number of electrons transferred for the balanced redox couple

F is the Faraday constant (coulombs mol<sup>-1</sup>)

The higher positive value of  $\Delta G^\circ$  presents more endothermic reaction, the reaction of  $\text{CO}_2$  reduction to  $\text{CH}_3\text{OH}$  and  $\text{CH}_4$  that are hydrocarbon fuels have highly endothermic status when compared with water-splitting reaction. Hence, conclude that  $\text{CO}_2$  RR is more thermodynamically unfavorable at ambient temperature.

Therefore, the effect of thermodynamic reactions of  $\text{CO}_2$  reduction is concerned to design the optimum operating conditions for specified products. Tables 2 and 3 show redox potentials of  $\text{CO}_2$  RR to some of the possible value-added products that were evaluated under room temperature, 1 atm for gases, and activity of 1 for the solute.

**Table 2.** Some of the possible products and thermodynamics of water splitting reaction and  $\text{CO}_2$  RR, standard electrode potentials ( $E^\circ$ ) based on normal hydrogen electrode (NHE) at pH=7 [4].

Reaction	Products	$\Delta E^\circ$ (V) vs. NHE at pH7
$2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2$	Hydrogen	-0.41
$\text{H}_2\text{O} + 2\text{h}^+ \rightarrow 1/2\text{O}_2 + 2\text{H}^+$	Oxygen	0.82
$\text{CO}_2 + \text{e}^- \rightarrow \text{CO}_2^{\cdot-}$	$\text{CO}_2^{\cdot-}$ intermediate	-1.9
$\text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{CO} + \text{H}_2\text{O}$	Carbon monoxide	-0.53
$\text{CO}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{HCOOH}$	Formic acid	-0.61
$\text{CO}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow \text{CH}_2\text{O} + \text{H}_2\text{O}$	Formaldehyde	-0.48
$\text{CO}_2 + 6\text{H}^+ + 6\text{e}^- \rightarrow \text{CH}_3\text{OH} + \text{H}_2\text{O}$	Methanol	-0.38
$\text{CO}_2 + 8\text{H}^+ + 8\text{e}^- \rightarrow \text{CH}_4 + 2\text{H}_2\text{O}$	Methane	-0.21

**Table 3.** Some of the possible products and thermodynamic half-reaction of CO<sub>2</sub> RR, standard electrode potentials (E°) based on standard hydrogen electrode (SHE) at pH=7 [17].

Half-reaction of CO <sub>2</sub> reaction	Products	E° (V) vs. SHE at pH7
$\text{CO}_2(\text{g}) + \text{H}_2\text{O}(\text{l}) + 2\text{e}^- = \text{CO}(\text{g}) + 2\text{OH}^-$	Carbon monoxide	-0.520
$\text{CO}_2(\text{g}) + 2\text{H}_2\text{O}(\text{l}) + 2\text{e}^- = \text{HCOOH}(\text{l}) + 2\text{OH}^-$	Formic acid	-0.610
$\text{CO}_2(\text{g}) + 3\text{H}_2\text{O}(\text{l}) + 4\text{e}^- = \text{CH}_2\text{O}(\text{l}) + 4\text{OH}^-$	Formaldehyde	-0.480
$\text{CO}_2(\text{g}) + 5\text{H}_2\text{O}(\text{l}) + 6\text{e}^- = \text{CH}_3\text{OH}(\text{l}) + 6\text{OH}^-$	Methanol	-0.380
$\text{CO}_2(\text{g}) + 6\text{H}_2\text{O}(\text{l}) + 8\text{e}^- = \text{CH}_4(\text{g}) + 8\text{OH}^-$	Methane	-0.240
$2\text{CO}_2(\text{g}) + 10\text{H}_2\text{O}(\text{l}) + 14\text{e}^- = \text{C}_2\text{H}_6(\text{g}) + 14\text{OH}^-$	Ethane	-0.270
$2\text{CO}_2(\text{g}) + 9\text{H}_2\text{O}(\text{l}) + 12\text{e}^- = \text{C}_2\text{H}_5\text{OH}(\text{l}) + 12\text{OH}^-$	Ethanol	-0.33
$2\text{CO}_2(\text{g}) + 8\text{H}_2\text{O}(\text{l}) + 12\text{e}^- = \text{C}_2\text{H}_4(\text{g}) + 12\text{OH}^-$	Ethylene	-0.34
$3\text{CO}_2(\text{g}) + 13\text{H}_2\text{O}(\text{l}) + 18\text{e}^- = \text{C}_3\text{H}_7\text{OH}(\text{l}) + 18\text{OH}^-$	Propanol	-0.320

The reference electrode potentials of half-reactions can be mentioned as a hydrogen electrode that provides a normal hydrogen electrode (NHE) and a standard hydrogen electrode (SHE). The platinum (Pt) electrode is used for both referenced electrodes, but the difference between NHE and SHE is based on potential measurement in a specified solution. While NHE measures potential in 1 N (normal concentration, for protons: 1 N = 1 M) acid solution, SHE measures potential in an ideal solution. However, SHE can be concluded current standard of zero potential because temperature variation is constant [18].

The first procedure of CO<sub>2</sub> RR is a reduction of one electron to CO<sub>2</sub><sup>•-</sup> intermediate that has the highest negative E° (-1.9 V vs. NHE at pH=7) and is often investigated in this procedure as a rate-limiting step. To convert CO<sub>2</sub> to a particular product, excess voltage than E° or energy input is required to activate the reaction. The role of redox potentials from half-reactions in tables 2 and 3 is represented by the minimum voltages for CO<sub>2</sub> RR motivation.

Although the specific reactions are achievements, high-efficiency catalysts are desired because multielectron transfer suppresses the selectivity of value-added products [3, 17].

### 2.2.3 Chemical products from CO<sub>2</sub> RR

The economic analysis is considered to manage significant problems from the previous section, including the large redox potential of one electron to CO<sub>2</sub><sup>•-</sup> intermediate and multielectron transfer. The economic analysis relates to operating costs and earnings from the production process. Table 4 shows the estimated market price, market size, and annual global production in USD: United States Dollars [3].

**Table 4.** Estimated market price (in USD/kg), normalized price (in USD/electron), market size (in USD/year), and annual global production (in million tons of CO<sub>2</sub>/year; Mtons) of major CO<sub>2</sub> reduction products [19, 20].

Products	Number of required electrons	Market price (\$/kg)	Normalized price (\$/electron) x 10 <sup>3</sup>	Estimate market size (\$/year)	Global production (Mtons/year)
Carbon monoxide (syngas, CO)	2	0.06	0.8	2.7-3.2	150.0
Carbon monoxide (CO)	2	0.6	8.0	-	-
Formic acid (HCOOH)	2	0.74	16.1	0.62	0.6
Methanol (CH <sub>3</sub> OH)	6	0.58	3.1	54	110.0
Methane (CH <sub>4</sub> )	8	0.18	0.4	-	250.0
Ethylene (C <sub>2</sub> H <sub>4</sub> )	12	1.30	3.0	155-248	140.0
Ethanol (CH <sub>3</sub> CH <sub>2</sub> OH)	12	1.00	3.8	-	77.0
N-propanol (CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> OH)	18	1.43	4.8	-	0.2

**Table 5.** Some applications of major CO<sub>2</sub> reduction products [3, 20].

Products	Applications
Carbon monoxide (CO)	<ul style="list-style-type: none"> <li>- Fuels and fuel additives</li> <li>- Plasticizer</li> </ul>
Formic acid (HCOOH)/Formate (HCOO <sup>-</sup> )	<ul style="list-style-type: none"> <li>- Food additives</li> <li>- Bleaching agent</li> </ul>
Methanol (CH <sub>3</sub> OH)	<ul style="list-style-type: none"> <li>- Fuel and fuel additives</li> <li>- Plastics industry</li> </ul>
Methane (CH <sub>4</sub> )	<ul style="list-style-type: none"> <li>- Fuels and fuel additives</li> <li>- Hydrogen production</li> </ul>
Ethylene (C <sub>2</sub> H <sub>4</sub> )	<ul style="list-style-type: none"> <li>- Precursor to polymers</li> <li>- Petroleum production</li> </ul>
Ethanol (CH <sub>3</sub> CH <sub>2</sub> OH)	<ul style="list-style-type: none"> <li>- Fuels and related products</li> <li>- Medical antiseptic, beverage</li> </ul>
N-propanol (CH <sub>3</sub> CH <sub>2</sub> CH <sub>2</sub> OH)	<ul style="list-style-type: none"> <li>- Fuels and fuel additives</li> <li>- Paint and coating additives</li> </ul>

From tables 4 and 5, CO and HCOOH/ HCOO<sup>-</sup> are interesting products because of their market growth rate and a variety of applications. Technavio [21] presented the global carbon monoxide alarm market from 2021 to 2025 which end-user includes industrial, commercial, and residential. The compound annual growth rate (CAGR) of the carbon monoxide alarm market from 2021 to 2025 is almost 8%. Besides, the incremental growth is predicted to be \$305.50 million. CO is also known as a key reaction intermediate on the route to C<sub>2+</sub> compounds which CO can be used in many applications such as fuel gas mixture with hydrogen for industrial, production of various chemicals (acids, esters, and alcohols) [22]. Likewise, as per Fact.MR [23] offered the global market research for the compound annual growth rate (CAGR) of formic acid from 2021 to 2031 equals 4%. The market size value of formic acid in 2020 was informed at \$1.5 billion and in 2031 is estimated to be \$3 billion. HCOOH/HCOO<sup>-</sup> can be used in many applications such as the

pharmaceutical industry, textile industry, rubber production, and animal feed. Moreover, HCOOH/ HCOO<sup>-</sup> is widely used as a catalyst in the production of various chemicals.

## 2.3 Strategies of CO<sub>2</sub> utilization

Many strategies for CO<sub>2</sub> conversion were developed due to the increase in CO<sub>2</sub> concentration which is the major fraction of GHGs. The obstacle in thermodynamic and kinetic properties of CO<sub>2</sub> molecules leads chemical and physical routes to be applied to utilized CO<sub>2</sub> materials. In this study, chemical routes are concerned wherewith CO<sub>2</sub> is direct converted. Many chemical routes have been studied that are related to thermochemical, biochemical, electrochemical, and photoelectrochemical [5].

### 2.3.1 Thermochemical CO<sub>2</sub> conversion

#### 1. Hydrogenation technology

The hydrogenation technology is the major destination of thermochemical CO<sub>2</sub> conversions, H<sub>2</sub> is used as a co-reactant to reduce stable molecules like CO<sub>2</sub>. A large amount of energy input is also acquired to provide value-added products such as CO, CH<sub>3</sub>OH, CH<sub>4</sub>, and C<sub>2+</sub> at relatively low temperatures (≤523 K) [24].

Methanol (CH<sub>3</sub>OH) is widely used as fuel for internal combustion so increasing demand in the global market occurs. However, a suitable catalyst is required to define strong equilibrium limitations by 220-250 °C to produce CH<sub>3</sub>OH via thermal CO<sub>2</sub> hydrogenation operating under high pressure of syngas (50-100 bars) which shows in reaction (1) [25].

X. Jiang et al. [26] presented the progress of CO<sub>2</sub> hydrogenation to CH<sub>3</sub>OH through heterogeneous catalysis. The catalytic performance and long-term stability are represented as performance indicators of diverse catalysts consisting of metals, metal oxides, and intermetallic compounds. Moreover, mechanics and kinetics are

investigated to realize the importance of catalysts on CO<sub>2</sub> hydrogenation to the CH<sub>3</sub>OH process.

## 2. Reforming technology

Thermochemical for reforming CO<sub>2</sub> to syngas (mixture of H<sub>2</sub> and CO) is a high-cost technique because the rare metals consisting of Pt, Pd, Ir, Rh, Ru, Co, and Ni are used to catalyze the methanation of syngas after CO<sub>2</sub> and CH<sub>4</sub> are adsorbed that still sought high temperature to thermodynamically unfavorable of CO<sub>2</sub> molecules which shows in reaction (2) [27, 28].

CO<sub>2</sub> is consumed as an oxidizing agent in the dry methane reforming process. However, this process still has significant problems such as low selectivity and the deactivation of catalysts from coke deposition which is shown in reaction (3) methane cracking and (4) reverse boundary reaction [27, 28].

Apart from applying proper catalysts that have good performance for operating at high-temperature conditions, solar energy could be used to solve a large amount of energy input. The tri-reforming process integrated methane steam reforming in reaction (5), methane partial oxidation in reactions (6) to (7), and CO<sub>2</sub> reforming of methane, there are other alternatives to avoid coke deposition for the methanation process [29].

P. Livingston et al. [30] proffered a technology to reduce CO<sub>2</sub> through gamma radiation. The CO<sub>2</sub> was pressed underground in the deep wells, then liquid with high pressure was injected. This technology is environmentally friendly for CO production, reduction of fossil fuels consumption, and prevention of the deposited problem.

Nevertheless, economics and safety are considered more studied because H<sub>2</sub> is used as a reductant so fractional distillation is required to recover the valuable feedstock chemical and a fully instrumented cooling pond is required to support radiation safety.

### 3. Mineralization technology

The CO<sub>2</sub>-mineralization technology produces carbonates through the reaction between CO<sub>2</sub> with alkaline-earth metals for example calcium oxide (CaO) and magnesium oxide (MgO) that is major fractions of industrial solid waste (ISW). Natural minerals and industrial solid waste (ISW) such as coal fly ash, steel slag, phosphogypsum, and blast furnace slag are utilized as raw materials for CO<sub>2</sub> mineralization technology.

From mineral carbonation reaction (8) is a spontaneous exothermic and thermodynamically favorable process. To produce carbonates, silicate rocks are often employed as host rocks since provide a less reasonable cost for the products separation unit. At present, CO<sub>2</sub> mineralization has been achieved in the laboratory through the injection of CO<sub>2</sub> to host rock at ambient temperature and pressure. Moreover, the possibility and long-term sustainability are needed to be studied to scale up for mineral carbonation [31, 32].

#### 2.3.2 Electrochemical CO<sub>2</sub> conversion

The electrochemical technology is widely used in the water-splitting and CO<sub>2</sub> RR where the reaction occurs at the interface of electrode/electrolyte. To drive the thermodynamically stable molecule of CO<sub>2</sub>, the electrochemical CO<sub>2</sub> RR required an electrolyte as a proton donor a suitable electrocatalyst that is deposited on the electrode surface and an external electric field that is overpotential for a specific reaction. Besides, an ion-exchange membrane may assemble between two electrodes as a separator unit of products [5].

When  $\text{CO}_2$  molecules are adsorbed on the working electrode, the structure of linear  $\text{CO}_2$  molecules is reformed to active form due to sluggish kinetics of electrochemical reduction. Also, reformation of  $\text{CO}_2$  structure will produce overpotential on first electron transfer motivation. Electrocatalysts still have been studied to improve the selectivity of  $\text{CO}_2$  electrochemical reduction. X. Chang et al. [33] proposed that apart from Cu used as an electrocatalyst for CO production, many electrocatalysts were examined namely metals (Sn, Pd, Cu, Pt, etc.), layered transition metal dichalcogenides ( $\text{WS}_2$ ,  $\text{MoSe}_2$ , and  $\text{MoS}_2$ ), and heteroatom-functionalized carbonaceous catalysts (N-doped carbon nanofibers and graphene quantum dots).

### 2.3.3 Photoelectrochemical $\text{CO}_2$ conversion

**Figure 7.** Schematic showing the five fundamental steps in photocatalytic  $\text{CO}_2$  reduction [5, 34].

To improve the selectivity of  $\text{CO}_2$  RR, PEC for  $\text{CO}_2$  RR applied solar energy as renewable energy consumption and external electric field. The PEC process for  $\text{CO}_2$  utilization can follow five steps that were shown in figure 7, including light absorption, charge separation,  $\text{CO}_2$  adsorption, surface redox reaction, and product

desorption. First, the photons are absorbed on a photoelectrode surface that is deposited by a photocatalyst made of suitable semiconductors before electron and hole pairs are produced. Then, photogenerated electrons and holes separate and electrons transfer from the photoelectrode surface to the redox electrode surface where molecules of CO<sub>2</sub> were absorbed while holes are accumulated at the photoelectrode compartment. CO<sub>2</sub> reduction and oxygen evolution reactions (OER) occur at the redox-electrode and photoelectrode, respectively. Finally, the products from CO<sub>2</sub> and OER are desorbed after the process is complete [5, 34]. Some possible half-reaction of OER at anode compartments and CO<sub>2</sub> reduction at cathode to formic acid is shown in reactions (9) to (11), respectively. In addition, hydrogen evolution reaction (HER) is the side reaction of CO<sub>2</sub> reduction is also shown in reaction (12) [35].

Because of cooperation and the advantages of solar energy and electrolysis reaction, the PEC process can operate under mild conditions, consume less input energy, and work under environmentally friendly. To add extra supplements, the PEC cell for CO<sub>2</sub> RR could be coordinated with other applications. Z. Zheng et al. [36] presented the applied progress of PEC cells in different functions comprising wastewater treatment coupled with H<sub>2</sub> production, wastewater treatment coupled with H<sub>2</sub>O<sub>2</sub> production, wastewater treatment coupled with desalination, electricity supplied from wastewater treatment, and wastewater treatment coupled with CO<sub>2</sub> reduction. The PEC cells improved efficiency by replacing suspended photocatalysts with synthesized photocatalysts on photoelectrode and applying low voltage on counter-electrode. For the multifunction of PEC CO<sub>2</sub> reduction, the excess electrons were transferred to the cathode compartment to reduce CO<sub>2</sub> while pollutants were degraded by accumulated holes in the anode compartment.

Although PEC CO<sub>2</sub> reduction coupled with wastewater treatment can produce high-value products and treat wastewater, the effect of PEC cells configuration and components including photoelectrodes, counter-electrodes, supporting aqueous electrolyte, ion exchange membrane, and applied voltages requires more research to scale up the technology into industry process.

#### 2.3.4 Biochemical CO<sub>2</sub> conversion

Biological CO<sub>2</sub> RR involves applying enzymes as catalyst that can improve selectivity and efficiency. The high purity feedstocks of biochemical of CO<sub>2</sub> RR are not desired due to the impurity of the process not toxicity to an enzyme [5]. In addition, the integration of enzyme catalysis with solar energy can solve the high demand for an energy input of CO<sub>2</sub> RR.

J. Milano et al. [37] offered an alternative to reduce fossil fuel consumption, the photosynthetic microorganisms are biological processes related to CO<sub>2</sub> RR by utilizing solar energy for chemical energy. The microorganisms such as microalgae required minimum nutrients, and the biomass contents were dried and converted to fuel by other strategies. However, cultivation areas and the costs of the harvesting stages are still a limitation for CO<sub>2</sub> utilization.

From various CO<sub>2</sub> conversion routes, each route has different advantages and disadvantages that are appropriate for specific value-added products can be concluded in figure 8 and table 6.

Figure 8. Main products from various CO<sub>2</sub> conversion routes [38]

**Table 6.** Advantages and disadvantages of various CO<sub>2</sub> conversion routes [39].

CO <sub>2</sub> conversion routes	Advantages	Disadvantages
Thermochemical	<ul style="list-style-type: none"> <li>- High value-added products such as syngas can be reformed into liquid fuel.</li> </ul>	<ul style="list-style-type: none"> <li>- Require a large amount of energy.</li> <li>- Deactivation of catalysts.</li> </ul>

## 2.4 Conceptual design of photoelectrochemical CO<sub>2</sub> RR

To improve the performance of the PEC CO<sub>2</sub> process, the effective factors like light intensity, operating mode (batch reaction system and continuous flow reaction system), operating conditions (temperature, pressure, flow rate), bandgap (type of semiconductors as photocatalyst), pH (type of electrolyte), product separator (type of ion-exchange membrane), and cell configurations were reviewed in many pieces of research for laboratory scale. The arrangement and PEC cell geometric configuration of the main components include photoelectrode, counter-electrode, electrolyte, and ionic conducting membrane which are still challenging for investigation in the laboratory and pilot plant, therefore, the numerical study for CO<sub>2</sub> reduction should be applied to model and simulate the process [40].

### 2.4.1 Design of PEC cell

#### 1. H-type cell

The H-type cell operates via a batch reaction system that is widely used on a laboratory scale. This cell configuration is less expensive because of its easy operation and abundant materials of electrodes. Normally, the H-type cell is assembled with 2 chambers of cathode and anode compartments which are separated using an ionic conducting exchange membrane to provide high purity of products from the reaction. Besides, three electrodes are also assembled consisting of the working electrode (WE), reference electrode (RE), and counter-electrode (CE), the WE and RE exist in the cathode compartment while CE exists in the anode compartment which H-type as shown in figure 9 [20, 41].

Figure 9. H-type cell [41].

Before  $\text{CO}_2$  is fed as liquid feedstock that requires dissolution in catholyte, this technology still acquired low conversion efficiency. To obtain higher performance, the longer electrolysis time and smaller electrode compartment should be concerned.

To increase conversion efficiency, K. P. Kuhl et al. [42] proposed the modified H-type cell maximizing the ratio of the electrode surface area to electrolyte volume ( $S/V$ ). This strategy adjusted the form of electrodes in the conventional H-type cell to the plate to support with bulk catalysts that working and counter electrodes were placed in parallel directions at a small distance which as shown in figure 10. The results showed higher conversion efficiency because the uniform distribution of voltages has occurred.

**Figure 10.** Modified H-type cell [20].

Although the ratio of the electrode surface area to electrolyte volume ( $S/V$ ) was solved, the low solubility of  $\text{CO}_2$  in the liquid phase still hinders the high conversion of  $\text{CO}_2$  RR [42].

## 2. Microfluidic flow cell (MFC)

A microfluidic flow cell (MFC) provides continuous operation to increase the conversion of  $\text{CO}_2$  RR which as shown in figure 11. MFC solves mass transfer problems via feed as continuous flow to obtain a high reaction rate into the feedstock chamber that attaches to the backside of the cathode, besides the electrolyte chamber is located between the cathode and anode compartments [41].

**Figure 11.** Microfluid flow cell (MFC) [41].

For this flow cell,  $\text{CO}_2$  in the gas phase is supplied into the gas chamber before being reduced at the interface of the catalyst/electrolyte layer. However, the low conversion occurred due to the transfer of  $\text{CO}_2$  being limited. Therefore, a gas

diffusion electrode (GDE) is employed as electrodes to override the problem. GDE consists of three sections including a catalytic layer (CL), a gas diffusion layer (GDL), and a gas flow field. Applying GDE can improve the conversion of reaction because the hydrophobic property of GDL can hinder the clogging of electrolytes in the pores and support the transport of  $\text{CO}_2$  to the CL. Although the results from more chance for direct contact can increase selectivity due to the pH from electrolyte promoting the suitable environment for  $\text{CO}_2$  RR, the MFC is not easy to scale up due to the effect of different pressure on the structure [41].

The ionic conducting membrane is used to provide a more suitable environment for  $\text{CO}_2$  RR that increases the selectivity of  $\text{CO}_2$  RR. The ion exchange membrane is located between catholyte and anode chambers to separate products and prevent the accumulation of ions which as shown in figure 12 [43].

**Figure 12.** Membrane-based flow cell or polymer electrode membrane flow cell [40].

The ionic conducting membrane or polymer electrode membrane can sort into anion exchange membrane (AEM), cation exchange membrane (CEM), and bipolar membrane (BPM). The AEM serves to allow anions transfer from cathode to anode compartment, while the CEM conducts cations from anode to cathode, thus BPM allows cations and anion transfer to cathode and anode, respectively. Although

the existence of PEM can offer high selectivity, the PEM also causes a large ohmic loss and impurities production that decreases the performance of the PEC cell [43].

### 3. Membrane electrode assembly (MEA) flow cell

From the large ohmic loss between two electrodes and impurities production in catholyte in the polymer electrode membrane flow cell, the polymer electrode membrane flow cell rearranged the configuration of two electrodes to solve these problems. The configuration of membrane electrode assembly (MEA) flow cell sets to reduce the distance between the location of two electrodes which as shown in figure 13 [44].

**Figure 13.** Membrane electrode assembly flow cell (MEAFC) [41].

Apart from the rearrangement of two electrodes, the MEA can serve both phases of reactants. The routes of reactant feeding are classified into (i)  $\text{CO}_2$  dissolved in liquid catholyte/ liquid anolyte, (ii)  $\text{CO}_2$  in the gas phase/liquid electrolytes (catholyte and anolyte), and (iii) humidified gases fed to both electrodes. For humidified gases fed to both electrodes, external saturation of  $\text{CO}_2$  and two liquid electrolytes are applied which  $\text{CO}_2$  is saturated by using a pump to continuously circulate through liquid catholyte. The schematic diagram of  $\text{CO}_2$  RR to ethylene applied humidified gases fed to both electrodes which is shown in figure 14 [45].

**Figure 14.** Schematic diagram of the reduction CO<sub>2</sub> to ethylene using MEAFC [45].

A large amount of ohmic loss and low solubility of CO<sub>2</sub> can be solved via applying MEA flow cell leads to improve selectivity and performance of the PEC CO<sub>2</sub> RR system, this configuration is appropriate for scaling up. But, the reference electrode (RE) is not used, so an external electric field is required for MEA flow cells [45].

#### 4. Solid electrolysis cell (SOEC)

Besides remodeling the PEC cell configuration, the effect of operating conditions should be concerned. Some value-added products are appropriate to operate under high-temperature conditions. The solid electrolysis cell (SOEC) used a solid electrolyte to transfer carrier ions coupled with porous anode and cathode which as shown in figure 15 [20].

**Figure 15.** Solid electrolysis cell (SOEC) [20].

Applying SOEC for high-temperature reactions requires heat that can be consumed as waste heat, this process can decrease external electrical field and drive kinetics of reactions to provide high conversion of CO<sub>2</sub> RR. But the SOEC limits the multiple products from CO<sub>2</sub> RR due to high-temperature results in immediate desorption of some species occurring [20, 46].

From the study of PEC cell design, the advantages and disadvantages were summarized in table 7.

**Table 7.** The advantages and disadvantages of each reactor design [20, 41, 47].

Type of reactor design		Advantages	Disadvantages
H-type cell (Batch)	H-type cell	<ul style="list-style-type: none"> <li>- Low cost</li> <li>- Widely uses on a laboratory scale.</li> <li>- Wide range of electrode</li> </ul>	<ul style="list-style-type: none"> <li>- Mass transport limitation</li> <li>- Less liquid products cannot be detected.</li> </ul>
	Modified H-type cell	<ul style="list-style-type: none"> <li>- High S/V ratio to define liquid products.</li> </ul>	<ul style="list-style-type: none"> <li>- Electrodes form limitation</li> <li>- Bubble formation hinders mass transport.</li> </ul>

#### 2.4.2 Performance indicators of PEC CO<sub>2</sub> RR

To define the optimum operating conditions, the PEC CO<sub>2</sub> RR was examined in different operating conditions and cell configurations due to various effective factors of the system such as light intensity, bandgap, flow rate, geometric PEC cell, and other operating conditions. The efficiency performance of PEC CO<sub>2</sub> RR can be expressed in various forms including CO<sub>2</sub> conversion, faradaic efficiency, current density, and energy efficiency as based indicators for comparing the performance of PEC CO<sub>2</sub> RR in various conditions.

##### 1. CO<sub>2</sub> conversion

CO<sub>2</sub> conversion ( $X_{CO_2}$ ) is defined as a ratio of the amount of CO<sub>2</sub> reactant that can be reacted to chemical products to the amount of CO<sub>2</sub> reactant. For continuous processes,  $X_{CO_2}$  can be calculated by Eq. 2.

$$X_{CO_2} = \frac{F_{CO_2,0} - F_{CO_2}}{F_{CO_2,0}} \quad \text{Eq. (2)}$$

where  $F_{CO_2,0}$  is the initial molar flow rate of CO<sub>2</sub> (mol/s)

$F_{CO_2}$  is the final molar flow rate of CO<sub>2</sub> (mol/s)

##### 2. Selectivity of desired product

Selectivity ( $S$ ) is the number of moles of interested product formed per the number of moles of overall products formed. Selectivity can be calculated by Eq. 3.

$$S = \frac{\text{Moles formed of interested product}}{\text{Moles formed of overall products}} \quad \text{Eq. (3)}$$

##### 3. Faradaic efficiency (FE)

Faradaic efficiency (FE) indicates the amount of fuel consumption with the amount of obtained current. The FE for PEC CO<sub>2</sub> reduction can be defined as a ratio of the current that promotes CO<sub>2</sub> conversion into chemical fuels to the received current. In addition, FE also shows the amount of electric consumption to produce desired products over the amount of charge transfer in the system, which can be calculated by Eq. (4) [6].

$$\begin{aligned}
 \text{FE}(\%) &= \frac{e_{\text{output}}}{e_{\text{input}}} \times 100\% \\
 &= \frac{n \text{ (mol)} \times y}{\frac{Q \text{ (Coulomb)}}{F \left( \frac{\text{Coulomb}}{\text{mol}} \right)}} \times 100\%
 \end{aligned}
 \tag{Eq. (4)}$$

where  $n$  is the number of moles of the desired product

$y$  is the number of electrons needed to convert  $\text{CO}_2$  into the desired product

$Q$  is the calculated electric charge (Coulomb)

$F$  is the Faraday constant (96485 Coulombs/mols of desired product)

The high FE can be mentioned to the high selectivity of  $\text{CO}_2$  RR to desired products, resulting in low cost due to the unnecessary product separation unit.

#### 4. Current density

The current density or density of an electric current represents the amount of electric charge flow (amperes) per the projected area of the photoelectrode (unit:  $\text{cm}^2$ ). The amount of electric charge transfer in the reaction is directly proportional to the number of products that occurred, or reactants consumed. When current density increases, it can refer to the consumption rate of reactants that is increasing. In particular, when the partial current density increases, it can refer to the increase in production rate of products concerned [47].

#### 5. Energy efficiency (EE)

The energy efficiency (EE) of the interested product is the amount of the electric energy that is supplied to the cell for interested product formation, which can be calculated by Eq. (5) [6].

$$\begin{aligned}
 \text{EE}(\%) &= \frac{\text{Productivity (mol s}^{-1}) \cdot \Delta H_{\text{comb}}^{\circ} (\text{J mol}^{-1})}{I_{\text{cell}} (\text{A}) \cdot E_{\text{cell}} (\text{V})} \times 100 \\
 &= \text{FE}(\%) \times \frac{E_{\text{therm}} (\text{V})}{E_{\text{cell}} (\text{V})}
 \end{aligned}
 \tag{Eq. (5)}$$

where  $\Delta H_{\text{comb}}^{\circ}$  is the combustion energy under standard conditions

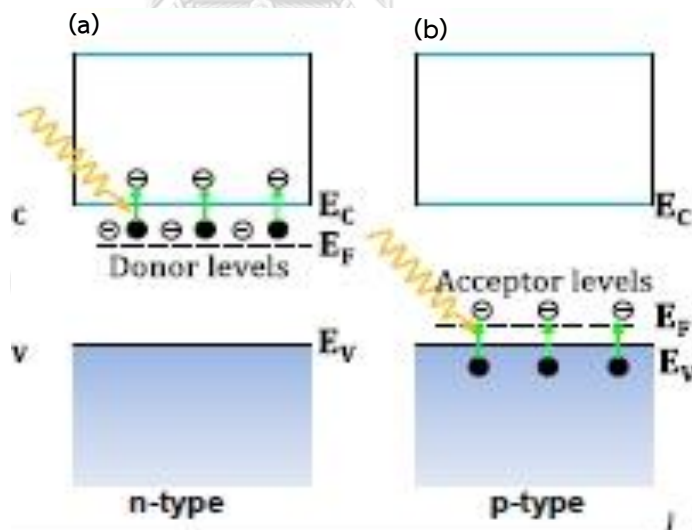

$E_{\text{therm}}$  is the thermoneutral voltage

## 2.5 Components of PEC cell

As well as the effect of the arrangement of PEC cell configuration, the component of the PEC cell is considered because the PEC reaction occurs on the interface of electrode and electrolyte. The suitable environment on the PEC cell should provide for high efficiency of PEC CO<sub>2</sub>RR. After this, the components of the PEC cell including photoelectrode, electrochemical electrode, and electrolyte are reviewed to study the effects of each component on the efficiency of electrochemical CO<sub>2</sub>RR.

### 2.5.1 Photoelectrode

The electrode can define as an electrical conductor which employs electric currents carrying to the non-metallic section that is an electrolyte, a semiconductor, and air. Besides, the photoelectrode which is applied for light absorption and free electron and hole transportation, types of photoelectrode are classified by configuration and mechanism of charge carriers, as described below:

**Figure 16.** The schematic of charge carrier mechanism of photoelectrochemical cell (PEC) based on (a) n-type semiconductor and (b) p-type semiconductor [48].

Note:  $E_v$ ,  $E_c$ , and  $E_f$  denote energy levels of valence band, conduction band, and Fermi energy level, respectively. Fermi level is the highest energy level of an energy at absolute zero temperature or the surface level where electrons do not have enough energy to rise above.

**Figure 17.** The schematics of (a) P-type semiconductor as photocathode (b) N-type semiconductor as photoanode and (c) Z-scheme with semiconductors as photocathode-photoanode [24].

### 1. Photocathode-Dark anode

From figures 16(a) and 17(a), the p-type semiconductor and metal are applied as photocathode and dark anode, respectively. The p-type semiconductor which is one of the extrinsic semiconductors has negative potential higher than the half-cell reduction reaction. The major charge carrier of p-type semiconductors is holes ( $h^+$ ) or acceptor impurity doped, electrons transfer from p-type semiconductors to reducing surface and holes move back to the interface of photocathode/electrolyte. The Fermi level of the p-type semiconductors locates close to the top of valence band (VB) which is less than the intrinsic semiconductor. The efficiency of p-type semiconductors is relatively low; therefore, a bias potential is required for the half-cell oxidation reaction. The metal-doped on intrinsic semiconductors of p-type such as boron (B), aluminium (Al), gallium (Ga), lead (Pb), Ag (silver), Au (aurum), Pd (palladium), Cu (Copper), and Ni (nickel) [24]. However, p-type semiconductors are costly, less stable, and toxic, thus, are still challenging to improve the efficiency of p-type semiconductors as photocathodes.

The p-type semiconductors as photoelectrode have been studied in many experiments to obtain more positive potential for oxidation reaction. For example, S. Kaneco et al. [49] presented the efficiency of PEC CO<sub>2</sub> RR in which CO<sub>2</sub> was saturated in a methanol-based electrolyte using a flow cell configuration. The flow cell with a methanol-based electrolyte of this experiment comprised a p-InP photocathode immersed in LiOH as catholyte, Ag/AgCl sat KCl as reference electrode, Nafion-117 as ion exchange membrane, and Pt-dark anode immersed in KOH as anolyte, respectively. In addition, 5000 W of Xe lamp ( $\lambda > 300\text{nm}$ ) was illuminated on the p-InP photocathode. The p-InP photocathode immersed in methanol-based electrolyte applied more positive potential versus the reference electrode to obtain desired products when compared with other metallic electrode systems. The results showed 41.5% and 15.0% faradaic efficiencies of CO and HCOO<sup>-</sup> were presented at -2.5 V vs. Ag/AgCl sat KCl, respectively.

Moreover, X. Huang et al. [50] demonstrated PEC CO<sub>2</sub> RR through Ru(bpy)<sub>2</sub>dppz-Co<sub>3</sub>O<sub>4</sub>/CA as a p-type semiconductor photocathode with graphite plate as a dark anode. The hybrid interface of the photocathode of this experiment included Co<sub>3</sub>O<sub>4</sub>, Ru(bpy)<sub>2</sub>dppz-, and CO<sub>2</sub> were supplied for light energy harvesting, mediation of the electron transportation, and substrate activation. For energy supply, the Xe lamp ( $\lambda > 420\text{nm}$ ) was illuminated on Co<sub>3</sub>O<sub>4</sub>, Ru(bpy)<sub>2</sub>dppz photocathode. The results showed the FE of HCOO<sup>-</sup> at -0.60 V vs. NHE reached 86% which consumed more positive than the thermodynamic potential of CO<sub>2</sub>RR to HCOO<sup>-</sup>.

In conclusion, the p-InP photocathode immersed in a methanol-based electrolyte can reduce the electrical energy consumption of PEC CO<sub>2</sub> RR which is a good offer for scaling up to industrial production.

## 2. Photoanode-Dark cathode

From figures 16(b) and 17(b), the n-type semiconductor and metal are applied as photoanode and dark cathode, respectively. The n-type semiconductor which is one of the extrinsic semiconductors requires low external bias to support the half-cell reduction reaction. The major charge carrier of n-type semiconductors is electrons ( $e^-$ ) or donor impurity doped, holes transfer from n-type semiconductors to the oxidizing surface and electrons move to bulk which back to the interface of cathode/electrolyte. The Fermi level of the n-type semiconductors locates close to the bottom of conduction band (CB) which is more than the intrinsic semiconductor. The efficiency of n-type semiconductors is relative to the concentration of electrons more than the band gap; therefore, n-type semiconductors respond to current conduction. The metal-doped on intrinsic semiconductors of n-type such as phosphorus (P), arsenic (As), antimony (Sb), and bismuth (Bi). The n-type semiconductors are inexpensive, earth-abundant, and highly stable [24]. Although, the good activity of electrocatalyst on the dark cathode is desired to obtain high product selectivity from this configuration.

The activity of photocatalysts and electrocatalysts was focused to obtain high efficiency of PEC cells and high selectivity for  $\text{CO}_2$ RR. G. Magesh et al. [51] proposed PEC systems for  $\text{CO}_2$ RR via flow cell configuration which using  $\text{WO}_3$  as a photoanode, electrocatalysts of  $\text{CO}_2$ RR as a cathode, and KCl as an electrolyte operated under the illumination of a 500 W Hg lamp ( $\lambda > 420\text{nm}$ ). The  $\text{WO}_3$  was utilized due to high activity and stability for oxygen evolution reaction (OER). The electrocatalysts of  $\text{CO}_2$ RR were Cu and Sn/ $\text{SnO}_x$  which were utilized due to high selectivity for  $\text{CO}_2$ RR to  $\text{CH}_4$  and CO and  $\text{HCOO}^-$ , respectively. The results via the PEC system of  $\text{WO}_3$  photoanode with Cu cathode indicated a 67%  $\text{FE}_{\text{CH}_4}$  at -0.75 V vs. RHE while  $\text{WO}_3$  photoanode with Sn/ $\text{SnO}_x$  cathode indicated a 15.9%  $\text{FE}_{\text{CO}}$  and 27.5%  $\text{FE}_{\text{HCOOH}}$  at -0.80 V vs. RHE. In addition, I. E. Irem et al. [52] improved the efficiency of PEC  $\text{CO}_2$ RR using  $\text{TiO}_2$  photoanode and Sn-GDE cathode operated under the illumination of a 300

W Xe lamp. To increase the concentration and mass transfer of substrate, the gaseous  $\text{CO}_2$  was direct fed Sn-GDE cathode to the filter-press flow cell. The results demonstrated 64%  $\text{FE}_{\text{HCOOH}}$  and 70%  $\text{EE}_{\text{HCOOH}}$  when a 1.2 V bias potential is applied.

To summarize, the overall efficiency of the photoanode-dark cathode system depends on efficiency from both half-cell oxidation and reduction. The low bias potential under visible light irradiation is enough to drive the overall efficiency of the photoanode-dark cathode system.

### *3. Photocathode-Photoanode*

From figure 17(c), the integration of two photoelectrodes also known as Z-scheme including the p-type semiconductor and n-type semiconductor for  $\text{CO}_2$  reduction and  $\text{H}_2\text{O}$  oxidation. The p-type semiconductor or photoanode should have negative potential higher than n-type semiconductor or photocathode to provide electrons transportation from photoanode to photocathode. The photocathode and photoanode can excite holes and electrons, respectively. The Z-scheme configuration is self-biased with potential voltage supporting from the difference value between of Fermi levels of photocathode and photoanode [53]. Therefore, the suitable semiconductors are required for Z-scheme to approve the half-cell reactions.

Because without bias potential configuration, the evolution of PEC through Z-scheme configuration was investigated with many photocatalysts to accomplish high efficiency. T. Morikawa et al. [54] offered a novel hybrid photocatalyst for PEC applied to photoanode-photocathode or Z-scheme configuration. Novel hybrid photocatalysts consisting of  $\text{TiO}_2$  which was employed as a photoanode and  $\text{InP/Ru}$  complex was employed as a photocathode for water oxidation and  $\text{CO}_2$  RR, respectively. Under free electrical bias potential and simulated light illumination conditions (1 sun, Air mass 1.5), the FE of  $\text{HCOO}^-$  could reach 75% at -0.6 V vs. NHE. Besides, B. Weng et al. [55] represented high catalytic activity for PEC through Z-scheme configuration. To obtain  $\text{TiO}_2$  NWs@CoP/CN as a photoanode and Si

NWs@CoP/CN as a photocathode, the CoP wrapped with porous N-doped carbon network (CoP/CN) nanocatalyst was consumed to coated TiO<sub>2</sub> nanowires (TiO<sub>2</sub> NWs) and p-type Si nanowires (Si NWs). The bifunctional of CoP/CN is high activity and stability for water oxidation and CO<sub>2</sub> RR, also the FE of CO could reach 90% at -0.15 V vs. RHE.

To conclude from the previous literature reviews, the Z-scheme without external electric bias plays an important role in saving energy consumption for the PEC system. However, the proper semiconductor photoelectrodes should be concerned to prevent side products from high potential providing.

Lastly, to illustrate the difference between photoelectrode configurations, advantages and disadvantages, a summary of the literature reviews is shown in tables 8 to 10.

**Table 8.** The difference between p-type semiconductor and n-type semiconductor [24].

	Photocathode-Dark anode (P-type semiconductor)	Photoanode-Dark cathode (N-type semiconductor)
Also known as	Acceptor impurity	Donor impurity
Major charge carriers	$h^+$	$e^-$
Minor charge carriers	$e^-$	$h^+$
Doped group	Group III elements. For example: B, Ga, Al, and Ni etc.	Group V elements. For example: P, As, Sb, and Bi etc.

**Table 9.** Advantages and disadvantages of different photoelectrode configurations [24, 53].

Photoelectrode configurations	Advantages	Disadvantages

For this study, the photoanode-dark cathode configuration was applied because it can reduce the external bias consumption and sustain stability in aqueous solutions. The photoanode are made of a thin film of metal oxide supported on a transparent conducting oxide (TCO).

The photocatalysts are light absorbing materials that induce chemical reactions. The properties of photocatalysts can affect PEC performance because photocatalyst can convert solar energy or light energy into electrical energy which can promote high potential on the cathode surface [56]. The good properties of photoactive semiconductor used as photoanode for chemical conversion application should have high negative potential than the potential of interested half-cell reaction to thermodynamically support oxidation and reduction reactions of hole and electron, respectively. Moreover, the activity, conductivity, and stability of the photocatalyst should be high enough to promote the half-cell reaction on photoelectrode [57].

Titanium dioxide ( $\text{TiO}_2$ ) is the one of the n-type semiconductors and the most common photocatalyst due to its wide band gap (3.20, 3.02, and 2.96 eV for anatase, rutile, and brookite phases, respectively), high resistance to photo-corrosion, non-toxicity, earth abundant, and low production cost [58, 59].

The applied bias potential is required for  $\text{CO}_2$  conversion to chemical products with high faradaic efficiencies. Many researchers investigated  $\text{TiO}_2$  as a photoanode. K. Kobayashi et al [56] revealed the experimental of conventional flow cell PEC  $\text{CO}_2$  RR to CO. The  $\text{TiO}_2$  semiconductor was used as a photoanode to absorb photocurrent from simulated UV illumination using 300 W Hg lamp and Ni phthalocyanine (NiPc) catalyst deposited on GDE as a cathode. In addition, 0.1 M  $\text{Na}_2\text{SO}_4$  and 1 M  $\text{Na}_2\text{SO}_4$  were consumed as anolyte and catholyte, respectively. The results presented FE of CO reaching 98% under UV light illumination and -0.8 V of bias potential.

Utilization of TiO<sub>2</sub>-photoanode can increase electrode potential on the cathode due to the supply of high electrical energy. The properties of TiO<sub>2</sub>-photoanode are wide band gap energy and a high level of the conduction band, thus, the demand of photon absorption is high for electrons excitation to the conduction band of photoelectrode [57, 58]. However, the geometries of TiO<sub>2</sub>-photoanode like length and thickness should be concerned to reduce resistance at photoelectrode and overall ohmic polarization loss of the PEC system.

### 2.5.2 Electrochemical electrode

The cathodic electrode is used as an electrochemical electrode in this study. The electrocatalyst for CO<sub>2</sub> RR should have high activity, electrical conductivity, selectivity, and stability in aqueous solutions operated under ambient operating conditions. Tables 2 and 3 indicated the products from multistep of CO<sub>2</sub> RR depending on electrode potential. To obtain desired products, the intermediate species from CO<sub>2</sub> RR such as CO<sub>2</sub><sup>•-</sup> should be adsorbed and stabilized on the catalyst surface. Besides, the products from CO<sub>2</sub> RR such as CO and HCOO<sup>-</sup> should be smoothly desorbed from the active surface of the catalyst. Therefore, the electrocatalysts for CO<sub>2</sub> RR were considered to achieve high product selectivity. The categories of electrocatalysts for CO<sub>2</sub> RR can be divided using types of metal elements consisting of transition metal elements (Sc, Ti, Cr, Mn, Fe, Co, Ni, Cu, Zn, Mo, Cd, Ta, and Hg), noble metal elements (Pd, Ag, Ir, Pt, and Au), and p-block elements (Al, Ga, In, Sn, Sb, Tl, Pb, and Bi) [52, 60]. By the way, the categories of electrocatalysts for CO<sub>2</sub>RR can be divided using occurring products which were clarified as shown below:

**Figure 18.** The categories of electrocatalysts for CO<sub>2</sub> RR [52, 60].

### 1. The electrocatalysts for CO<sub>2</sub> RR to H<sub>2</sub>

Apart from multi-carbon products, H<sub>2</sub> is also a side product from CO<sub>2</sub>RR which is shown in reaction (12). The electrocatalysts that involve hydrogen evolution reaction (HER) are separated into inert and semi-inert. The inert electrocatalysts for HER which are not affecting reaction rate though operating conditions are adjusted comprising of Al, Mn, and Ta. Likewise, the semi-inert electrocatalysts for HER which affect the reaction rate when operating conditions are adjusted comprising of Ti, Fe, Ni, and Pt [52, 60].

### 2. The electrocatalysts for CO<sub>2</sub> RR to HCOOH

The electrocatalysts for CO<sub>2</sub> RR to formate ion, HCOO<sup>-</sup> (or HCOOH when operating in the acidic electrolyte) consist of In, Sn, Sb, Tl, Pb, Bi, Mo, Cd, and Hg. These electrocatalysts have high electrode potential to adsorb and stabilize intermediate species (CO<sub>2</sub><sup>•-</sup>) before reducing to desired products [52, 60].

### 3. The electrocatalysts for CO<sub>2</sub> RR to CO

The electrocatalysts for CO<sub>2</sub>RR to CO consist of Sc, Sr, Mn, Fe, Co, Ni, Cu, Zn, Ga, Y, Pd Ag, Sn, Sb, Ir, au, and Bi. To break the C-O bond, the electrode potential of these electrocatalysts is greater than HER but less than CO<sub>2</sub> RR to HCOOH. Besides, the catalyst should easily desorb CO from the active surface [52, 60].

### 4. The electrocatalysts for CO<sub>2</sub> RR to C<sub>x</sub>H<sub>y</sub>O<sub>z</sub>

The multi-carbon products include CH<sub>4</sub>, C<sub>2+</sub>, alcohols and aldehydes consisting of Co, Cu, and Zn. The activity of these electrocatalysts provides optimum CO adsorption and hydrogenation of adsorbed CO to CHO intermediate to obtain C<sub>x</sub>H<sub>y</sub>O<sub>z</sub>, especially Cu [52, 60].

The interested electrocatalysts for CO<sub>2</sub> RR to HCOO<sup>-</sup> are in the 2<sup>nd</sup> category in which the widely used catalysts include In, Sn, Pb, Bi, and Hg. These elements are compared to specify the suitable catalyst for CO<sub>2</sub> RR to HCOO<sup>-</sup> which are shown in table 11.

**Table 11.** The properties of the widely used electrocatalyst for CO<sub>2</sub> RR to HCOO<sup>-</sup> [61, 62].

Property Catalyst	Physical characteristics at ambient conditions	Density (kg·m <sup>-3</sup> )	GHS hazard statements	Market price (\$/kg)
In	Lustrous silvery solid metal	7.31 ×10 <sup>3</sup>	Not	222-225
Sn	Silvery white solid metal	7.28 ×10 <sup>3</sup>	Not	12-25.39
Pb	Silvery white or grayish solid metal	11.35 ×10 <sup>3</sup>	Slight	1.86-2.27
Bi	Silvery white solid metal	9.78 ×10 <sup>3</sup>	Not	15-39
Hg	Silvery white liquid metal	13.53 ×10 <sup>3</sup>	Acute	32-100

Note: GHS also known as Globally Harmonized System of Classification and Labelling of Chemicals

From table 11, the toxicity of In, Sn, Pb, and Bi are less toxic or even nontoxic than Hg when considered chemical hazards through GHS. In addition, the market prices of Sn, Pb, and Bi are quite minimal when compared with In and Hg.

Sn-based electrocatalysts are widely used in CO<sub>2</sub> RR to HCOO<sup>-</sup> due to their high selectivity and inexpensive. For example, D. Kopljar et al. [63] produced HCOO<sup>-</sup> at high current densities through a microfluidic flow cell (MFC) electrolyzer using Sn and SnO<sub>2</sub> deposited on gas diffusion electrodes (GDEs) were used as cathodes. First, nanoparticles of Sn and SnO<sub>2</sub> were examined to define characteristics and activities when coating on GDEs. From ex situ characterization, the diameter of SnO<sub>2</sub> nanospheres is wider than the diameter of Sn nanospheres. The activities of Sn-GDE and SnO<sub>2</sub>-GDE which controlled mass loading (0.35 mg•cm<sup>-2</sup>) were compared through current densities. The onset electrode potentials vs. Ag/AgCl of CO<sub>2</sub> RR derived from using SnO<sub>2</sub>-GDE is -1.29 V and Sn-GDE is -1.92 V. The current densities of CO<sub>2</sub> RR derived from using SnO<sub>2</sub>-GDE and Sn-GDE as cathode at onset potential vs. Ag/AgCl were 385±19 mA•cm<sup>-2</sup> and 216±6 mA•cm<sup>-2</sup>. Moreover, the production rates of HCOO<sup>-</sup> derived from 1-hour electrolysis using SnO<sub>2</sub>-GDE and Sn-GDE as cathodes at onset potential vs. Ag/AgCl are 14.9±0.8 mmol•m<sup>-2</sup>s<sup>-1</sup> and 7.4±0.6 mmol•m<sup>-2</sup>s<sup>-1</sup>, respectively. This experiment shows the FE of HCOO<sup>-</sup> could reach 79.00±3.13% and 70.00±3.99% for SnO<sub>2</sub>-GDE and Sn-GDE as cathodic electrodes. D. Thuy et al. [64] spent tin oxide (SnO<sub>2</sub>) nanospheres as electrocatalysts on CO<sub>2</sub> RR to HCOO<sup>-</sup>. To define the effect of calcination temperature, SnO<sub>2</sub> nanoparticles were investigated through flow cell configuration. The higher calcination temperature could increase the diameter of SnO<sub>2</sub> nanocrystals, SnO<sub>2</sub> nanospheres calcined at 500°C was selected as electrocatalyst because of their ability to prevent agglomeration and provide a large surface area. In addition, SnO<sub>2</sub> nanospheres were deposited on a gas diffusion electrode (GDE) which was used as a cathode operating in a membrane electrode assembly (MEA) electrolyzer. The FE and current density of HCOO<sup>-</sup> could reach

75±6% and 500 mA•cm<sup>-2</sup> at 1.41 V of equilibrium cell potential over 24 hours of electrolysis.

The high surface and activity of SnO<sub>2</sub> nanospheres can support the reason for scaling up the industrial production of CO<sub>2</sub> RR to HCOO<sup>-</sup>. Besides the performance of catalysts, the configuration of the MEA electrolyzer that has direct feeding gaseous CO<sub>2</sub> to the cathode and alkaline environments also improves the current density and selectivity of HCOO<sup>-</sup>.

### 2.5.3 Gas diffusion electrodes (GDEs)

The major limitations of the electrolyzer assembled with a planar electrode are low solubility of gaseous CO<sub>2</sub> in liquid electrolytes resulting in decreasing CO<sub>2</sub> conversion. Applying gas diffusion electrodes (GDEs) can improve the current density CO<sub>2</sub> conversion by solving the solubility of gaseous CO<sub>2</sub> in liquid electrolyte limitation and facilitating the transportation of reactive species to active sites [65, 66]. The schematic of GDE is shown in figure 19.

**Figure 19.** The schematic of GDE [67].

GDEs are porous electrodes made of assembling of porous catalyst layer with diffusion media. To support the three-phase interface (gas, liquid, and solid), GDEs comprise hydrophilic and hydrophobic sides. The three-phase interface is the contact boundary of the gaseous reactant, the liquid electrolyte, and the solid electrode. The hydrophilic side is dominant in the catalyst layer which provides the transport of ionic species and maximizes the active sites as a three-phase interface. And the

hydrophobic side is dominant in the diffusion layer which hinders flooding and blockage of the gas diffusion layer [68].

The usage examples of GDE on the electrochemical system, K. Wu et al. [69] demonstrated the computational modeling of the electrochemical CO<sub>2</sub> reduction to CO which this half-cell model at the cathode was simulated to evaluate the effective operating and design parameters of the microfluidic flow cell (MFC). The GDEs assembled with graphite current collector were used as electrodes for gaseous CO<sub>2</sub> feeding. The Pt blank-anode, aqueous KCl as electrolyte channel, and Ag-cathode were horizontally sandwiched in rectangular forms respectively. The electrochemical gaseous CO<sub>2</sub> RR model was assumed in isothermal and steady-state simulation through kinetics of charge species, mass, and momentum conservations. The current densities (CD) from the half-cell model were consistent with the experimental results. The results showed CD was improved, and faradaic efficiency (FE) was deduced when the negative applied voltage at the cathode was increased. Although increasing the feed concentration of CO<sub>2</sub> could increase the CD and FE, deducing of CO<sub>2</sub> conversion occurred. In addition, the longer cell was directly proportional to increasing CO<sub>2</sub> conversion, but the CD and FE were decreased. Y. Fu et al. [70] demonstrated a hierarchical SnO<sub>2</sub> microsphere coated on GDE (HMS-SnO<sub>2</sub>/GDE) as an electrode for CO<sub>2</sub> RR to HCOO<sup>-</sup> in aqueous solutions. The operating of the flow cell electrolyzer at -1.7 V vs. SHE could allow 62% FE<sub>HCOO<sup>-</sup></sub> over 12 hours of electrolysis. The synthesis of self-assembled SnO<sub>2</sub> microsphere catalysts via hydrothermal can improve the catalytic activity, coating catalysts on GDE also contributes to expanding surface area, decreasing the resistance between the gas-liquid interface and the catalyst surface, and hindering hydrogen evolution reaction (HER) by faster kinetics reaction.

Apart from that, the arrangement of GDE also impacts the performance of the electrochemical cell. H. Yang et al. [71] developed a new design configuration of the electrochemical cell to convert CO<sub>2</sub> to pure formic acid (HCOOH). The deionized (DI)

water substituted salt additions as an electrolyte and GDEs were used in the new design of an electrochemical cell that is divided into three compartments including an anode, center, and cathode compartments assembled in vertical following in a sequence from left to right. The cathode compartment was maintained in the alkaline environment to offer a reaction of CO<sub>2</sub> with DI water to formate ion (HCOO<sup>-</sup>) by assembling an anion exchange membrane with GDE while a CEM was assembled in an anode compartment for O<sub>2</sub> and protons (H<sup>+</sup>) production. Moreover, DI water was fed to the center compartment using strong acid cation exchange media for the reaction of HCOO<sup>-</sup> and H<sup>+</sup> derived from cathode and anode compartments respectively. The results showed the high current densities of 5-20 wt% HCOOH production equaled 140 mA•cm<sup>-2</sup> when low applied voltage (~3.5 V) is consumed. In addition, the high performance of this configuration could be presented through 500 hours of the experiment set up that can conclude scaling up to the industrial process.

However, the GDEs are currently widely used in electrochemical systems, and the improvement of GDE is still concerned to reduce the limitation of mass transportation that affect selectivity and stability of electrochemical reactions.

#### 2.5.4 Electrolyte จุฬาลงกรณ์มหาวิทยาลัย

The CO<sub>2</sub> RR occurs between the interface of the electrode/electrolyte. The roles of electrolytes directly affect the efficiency of the electrochemical system. Electrolytes are substances that carry ionic species when dissolved in water [72]. The effective factors of electrolytes in an electrochemical system consist of concentration, pH, cations, and anions [73] which are given in detail as bellows.

##### 1. Concentration

The optimum concentration of electrolyte can provide the high current efficiency of CO<sub>2</sub> RR. The dissociation of electrolyte performs the ions in solution, hydroxide ion (OH<sup>-</sup>) also obtain from dissociation reaction. The charge transfer

resistance ( $R_{ct}$ ) and the thickness of the electrical double layer (EDL) of the electrode can be reduced by absorbing on  $\text{OH}^-$  an active surface. The concentration of  $\text{OH}^-$  is increased when the supply has a higher electrolyte concentration [72, 73].

Q. Wang et al. [74] studied the effect of electrolyte concentration on  $\text{CO}_2$  RR to  $\text{HCOO}^-$  proceeding with direct gaseous  $\text{CO}_2$  feeding to Sn-GDE cathode with  $\text{KHCO}_3$  solution as a liquid electrolyte. The  $\text{KHCO}_3$  solutions were varied concentrations of 0.1, 0.3, 0.5, 0.7, and 0.9 M under the applied bias potential of -1.8 V. The tendency of partial current densities of  $\text{HCOO}^-$  increased when 0.1 M to 0.5 M  $\text{KHCO}_3$  solutions were consumed. While the tendency of partial current densities of  $\text{HCOO}^-$  decreased when 0.5 M to 0.9 M  $\text{KHCO}_3$  solutions were consumed. Moreover, the variation of faradaic efficiencies of  $\text{HCOO}^-$  when varied concentrations of  $\text{KHCO}_3$  solutions were the same trend as partial current densities. The maximum partial current density and FE of  $\text{HCOO}^-$  revealed  $17.43 \pm 2.60 \text{ mA} \cdot \text{cm}^{-2}$  and  $78.60 \pm 0.11\%$  with consumption of 0.5 M  $\text{KHCO}_3$  solution.

Similar to S. V. Kenis et al. [75] regarded variation of electrolyte concentration to the current efficiency of  $\text{CO}_2$  RR. The conversion of  $\text{CO}_2$  to CO in a flow cell assembled by Fe porphyrin mixed with carbon black deposited on carbon paper support as a cathode. The current density of CO was increased when the concentration of KOH electrolyte increased. The excess 2 M KOH electrolyte did not possess the higher current densities of CO.

Although the higher concentration of electrolyte can induce more  $\text{CO}_2$  RR, the mass transfer limitation interrupts the higher current efficiency since the excess electrolyte concentration. Therefore, the optimum electrolyte concentration is required to save cost when scaling-up industries are performed.

## 2. Potential hydrogen (pH)

The influence of the pH of the electrolyte on electrochemical CO<sub>2</sub> RR is high because the OH<sup>-</sup> on the electrode interface can be neutralized using bicarbonate buffers. The OH<sup>-</sup> is a product from CO<sub>2</sub> RR and HER, the local environment on the electrode surface of CO<sub>2</sub> RR can be changed by the concentration of OH<sup>-</sup> [72, 73]. The influence of pH can be described in equilibrium reactions of the CO<sub>2</sub> and bicarbonate which is shown in reactions (13) to (17).

When pH > 7,

The neutralization of OH<sup>-</sup> on the electrode surface.

From reactions (14a) and (14c), the CO<sub>2</sub> hydration can form bicarbonate buffer (HCO<sub>3</sub><sup>-</sup>), but the rates of reactions are very low which results in a very low concentration of H<sub>2</sub>CO<sub>3</sub>. However, the formation rate of HCO<sub>3</sub><sup>-</sup> is high along reaction (16) when the pH of the electrolyte is more than 10. Besides, the HCO<sub>3</sub><sup>-</sup> and CO<sub>3</sub><sup>2-</sup> are assumed in the balance due to the deprotonation rate is being high along reactions (14b), (15), and (17). Therefore, when the pH of the electrolyte is higher than 10, the amount of HCO<sub>3</sub><sup>-</sup> consumed as a proton donor is enough for CO<sub>2</sub> RR.

Because KHCO<sub>3</sub> solution is a buffer electrolyte which uses to sustain the local environment and neutral OH<sup>-</sup> from CO<sub>2</sub> RR as shown in the equilibrium reaction. The CO<sub>2</sub> RR to HCOO<sup>-</sup> is hindered when a low concentration of KHCO<sub>3</sub> solution or weak buffer solution is employed since pH of the local environment is high. The high concentration of KHCO<sub>3</sub> solution or strong buffer solution can sustain pH of the local environment and improve ionic conductivity [72, 73]. However, the optimum

concentration of  $\text{KHCO}_3$  solution is required for  $\text{CO}_2$  RR to  $\text{HCOO}^-$  because the excess concentration of  $\text{KHCO}_3$  solution provides a hydrogen evolution reaction (HER).

The experiment was exposed by Y. Fu et al. [70] with feeding saturated  $\text{CO}_2$  in aqueous electrolytes at  $-1.5$  V vs. SHE. To convert  $\text{CO}_2$  to  $\text{HCOO}^-$  in aqueous solutions, the flow cell including Pt foil,  $\text{SnO}_2/\text{GDE}$ , and Nafion-117 were used as anode, cathode, and membrane, respectively. The faradaic efficiency of  $\text{HCOO}^-$  when consuming an  $\text{H}_2\text{O}$  electrolyte with  $\text{CO}_2$  bubbling showed only 1.0%. The faradaic efficiency and concentration showed 56.02% and  $260 \text{ mg}\cdot\text{L}^{-1}$  when 0.5 M  $\text{KHCO}_3$  electrolyte replaced pure water-electrolyte. Although, a large amount of liquid  $\text{CO}_2$  is performed when consuming  $\text{H}_2\text{O}$  electrolyte with  $\text{CO}_2$  bubbling but providing hydrogen ions from  $\text{H}_2\text{O}$  as an aqueous electrolyte is not enough to conduct  $\text{HCOO}^-$  production on the active surface. On the contrary, 0.5 M  $\text{KHCO}_3$  electrolyte can the large amount of liquid  $\text{CO}_2$  and  $\text{HCO}_3^-$  which can enhance mass transfer diffusion and electrolytic conductivity of  $\text{CO}_2$  RR to of  $\text{HCOO}^-$  on the electrode surface.

However, the other buffer solutions were concerned to define the optimum performance of the  $\text{CO}_2$  RR system. J. B. Vennekötter, et al. [76] examined the effect of the local environment on electrolyte to the electrochemical system. To compare the effects of pH on  $\text{CO}_2$  conversion to CO were operated using a two-sided buffered cell. The two-sided buffered cell with directly supply gaseous  $\text{CO}_2$  was assembled Ag-GDE as a cathode, catholyte, CEM, 0.05M  $\text{H}_2\text{SO}_4$  as anolyte, and  $\text{TiO}_2$  coated on Pt as an anode in the x-direction from left to right. The different cathodic electrolytes displayed pHs variation consisting of a 0.5 M  $\text{K}_2\text{SO}_4$  electrolyte ( $\text{pH}\leq 4$ ), 0.1 M  $\text{KHCO}_3$  + 0.5 M  $\text{K}_2\text{SO}_4$  electrolyte ( $\text{pH}\approx 6.8$ ), 1.0 M  $\text{KHCO}_3$  electrolyte ( $\text{pH}\approx 8$ ), and 2.0 M  $\text{KHCO}_3$  electrolyte ( $\text{pH}\approx 8.8$ ). The results indicated the negative cathodic potentials were decreased when increasing pHs which related to the ionic strength of the electrolyte were supplied. For instance, the FEs of CO 90% were obtained when  $-1.0$  V vs RHE 0.5 M  $\text{K}_2\text{SO}_4$  electrolyte,  $-0.95$  V vs RHE 0.1 M  $\text{KHCO}_3$  + 0.5 M  $\text{K}_2\text{SO}_4$  electrolyte,  $-0.80$  V vs RHE 1.0 M  $\text{KHCO}_3$  electrolyte, and  $-0.81$  V vs RHE 2.0 M  $\text{KHCO}_3$  electrolyte. The

higher pH of the electrolyte could reduce the consumption of applied electric energies on the cathode.

The buffer solutions present the ionic strength of electrolytes. The high electrolytic conductivity of  $\text{HCO}_3^-$  displays the ohmic loss minimization in the electrolyte which leads to reducing the cathodic potential. Besides, the electrode overpotential also decreases when the cathodic electrode is used as the working electrode.

### 3. Cation

The effect of ionic species in the electrolyte is investigated as a function of the electrolyte composition. The significant effect of cation is derived from cation size on the product distributions of  $\text{CO}_2$  RR [72, 73]. According to the experiment of J. Resasco et al. [77], the alkali metal cations in the electrolyte were investigated on electrochemical  $\text{CO}_2$  to  $\text{HCOO}^-$  and CO regardless of the effects of concentration and pH of the electrolyte. The polycrystalline Ag and Sn were used as electrocatalysts. The current densities of  $\text{HCOO}^-$  and CO were increasing when the alkaline metal cations in the electrolyte increased ( $\text{Li}^+ < \text{Na}^+ < \text{K}^+ < \text{Rb}^+ < \text{Cs}^+$ ). In the same way, S. Sato et al. [78] proposed electrochemical  $\text{CO}_2$  RR with less energy consumption which used the integration of Mn-complex/multiwalled carbon nanotubes (Mn complex/MWCNT) as a cathode with  $\text{K}^+$  cation. The integration of Mn-complex/MWCNT with  $\text{K}^+$  cation could stabilize  $\text{CO}_2$  taken in active sites of the electrocatalyst.

As a result, when the cation is adsorbed on the electrocatalyst surface, the cation is served as a catalyst promoter. The cation with a larger size provides a weak hydration shell of the cation which facilitates cation adsorption on the catalyst surface. Hence, the catalytic activity and selectivity can be improved by offering the electrocatalyst with a larger size of cation.

#### 4. Anion

Anions from the dissociation of electrolyte also affect the performance of product selectivity from CO<sub>2</sub> RR system. From the previous details, the OH<sup>-</sup> and HCO<sub>3</sub><sup>-</sup> in alkaline electrolyte can hinder the HER because of providing high electrical conductivity and ohmic loss minimization [73, 75]. S. S. Bhargava et al. [79] showed effect of electrolyte composition on electrochemical CO<sub>2</sub> RR to CO. The degree of variation of FE<sub>CO</sub> relies on the anions as Cl<sup>-</sup> ≈ CO<sub>3</sub><sup>2-</sup> < HCO<sub>3</sub><sup>-</sup> ≤ OH<sup>-</sup>. And the degree of variation of current density of CO relies on the anions as Cl<sup>-</sup> < HCO<sub>3</sub><sup>-</sup> < CO<sub>3</sub><sup>2-</sup> < OH<sup>-</sup>. Thus, the anion which has a stronger pH-based overpotential demand provided the higher effect on current density of CO. While the anion which has a stronger specific adsorption on the electrode surface provided the higher effect on FE of CO.

The influences of other anions such as perchlorate, sulfate, phosphate, and borate on CO<sub>2</sub> RR to H<sub>2</sub> and CH<sub>4</sub> were also studied. M. N. Jackson et al. [80] investigated the effect of borate buffer and phosphate buffer on the Au electrode. The borate buffer and phosphate buffer were consumed as proton donors for CO<sub>2</sub> RR to H<sub>2</sub>. The existence of phosphate buffer could support the HER as a proton donor better than water, but in case that borate buffer did not. Besides, the appearance of perchlorate buffer and sulfate buffer as proton donors did not support HER and CH<sub>4</sub>. It appears that the role of the weak buffer anions which serve as a proton donor can utilize to suppress HER and CH<sub>4</sub> in electrochemical CO<sub>2</sub> reduction.

#### 2.6 Literature reviews

To simulate the behavior of PEC CO<sub>2</sub> RR, the effective factors of the system were studied through many types of research. Literature reviews can provide the optimum operating conditions to model and simulate via COMSOL Multiphysics (5.6). The literature reviews were described as follows and summarized in table 12.

Table 12. Summary of literature reviews.

Main characteristics	Electrodes	Operating conditions	Main products	Efficiency	Ref.
Electrochemical reaction via MFC without membrane [Modeling]	Anode: Pt Cathode: Cu <sub>2</sub> O-ZnO-GDE	Reactant: CO <sub>2</sub> saturated, Anolyte: 0.5 M KHCO <sub>3</sub> , Catholyte: 0.5 M KHCO <sub>3</sub> with flow rate 20 mL/min	CH <sub>3</sub> OH	Average error: 20.2%	Y. PEC reaction via H-type cell assembled with Z-scheme (photoanode+photocathode) [Experiment]	Photoanode: TiO <sub>2</sub> on Pt Photocathode: InP/Ru complex	Reactant/Electrolyte: NaHCO <sub>3</sub> with flow rate 0.01 mol/L, Light source: AM 1.5G Reaction time: 24 h	HCOO <sup>-</sup>	FE: >70%	T. Arai et al. (2011), [86]

The operating conditions and geometric configurations of PEC cells are also important effects on the efficiency of the process such as ion exchange membrane, gas diffusion electrode (GDE), liquid electrolyte, type of semiconductor, light intensity, flow rate, and arrangement of main components. The example of literature should be reviewed to provide the optimum parameters for modeling and simulation of the PEC CO<sub>2</sub> RR in the optimum.

Y. Kotb et al. [81] proposed the results from a simulation of the numerical model of electrochemical reduction of CO<sub>2</sub> to CH<sub>3</sub>OH using COMSOL Multiphysics through the finite element method. The microfluidic flow cell was separated into 3 portions including the Cu<sub>2</sub>O-ZnO gas diffusion electrode as a cathode, platinized titanium as an anode, and membrane. CO<sub>2</sub> was saturated and fed together with 0.5 M KHCO<sub>3</sub> as catholyte at the inlet of the cathode and 0.5 M KHCO<sub>3</sub> was also used as an anolyte to feed at the inlet of the anode with the flow rate of 20 ml/min. Then applied mass transport electrolytic species concentration, electrode reaction kinetics, and charge transport electric and ionic potential to simulate and validate comparing with the experimental data. The results from validation with the experimental data showed a 20.2% average error due to competition of hydrogen production, thus ionic conducting membranes were suggested to separate the desired product.

W. Lu et al. [82] presented the direct feeding of CO<sub>2</sub> in the gas phase to an Ag nanocube-based membrane cathode assembly to overcome the low solubility property in CO production. The system was set with WO<sub>3</sub>/BiVO<sub>4</sub> photoanode, KHCO<sub>3</sub> as an electrolyte under the illumination of a 300 W Xw arc lamp as simulated light intensity to vary the applied voltages. Due to high stable molecules of CO<sub>2</sub>, the results showed the optimum applied voltage should not be lower than 1.2 V could. The energy efficiency from the system of CO<sub>2</sub> reduction to CO coupled with obtained Ag nanocube-based membrane cathode assembly reached 92.1% this could provide a critical factor in the scaling-up process.

C. Akan et al. [83] evaluated a 2-dimensional numerical model to produce formic from the electrolysis of CO<sub>2</sub> using a microfluidic cell. This system applied CO<sub>2</sub> in the gas phase, Bi-Sn on GDE as cathode, Pt as an anode, and an ionic liquid as electrolyte was 1-ethyl-3-methyl imidazolium tetra-fluoroborate ([EMIM][BF<sub>4</sub>]) to improve the performance of the process. The microfluidic flow cell was separated into 3 portions, cathode, anode, and proton exchange membrane. The GDEs were provided for feeding CO<sub>2</sub> in the gas phase at the cathode and O<sub>2</sub> gas at the anode, GDEs were located on the top and bottom of the membrane, respectively. The model combined thermodynamics and kinetics through the calculation of species charge transport through electrochemistry, mass conservation, and momentum conservation. The results were analyzed from model validation, mass transport, and electrochemical from the process. This model obtained 60 mA/cm<sup>2</sup> of current density, 98% of faradaic efficiency, and 80% of CO<sub>2</sub> reduction to formic acid due to suppression of hydrogen evolution reaction of ionic liquid that could use as a reference in the scaling-up process through improvement of the current density of formic acid.

E. Irtem et al. [84] investigated the effect of light intensity and geometry of cathode through PEC CO<sub>2</sub> conversion to HCOO<sup>-</sup> and oxygen (O<sub>2</sub>) production at the cathode and photoanode compartments, respectively that separating by the membrane. To improve concentration and mass transfer, CO<sub>2</sub> in the gas phase was saturated via catholyte before feeding and circulated using a pump. The catholyte and anolyte were applied to neutral the process were 0.5 M NaHCO<sub>3</sub> and 0.5 M NaOH, respectively. The PEC CO<sub>2</sub> conversion was evaluated through filter-press flow cell using TiO<sub>2</sub>-photoanode coupled with deposited Sn on GDE used as cathode under back-illumination of visible light. Besides, varying the ratio of photoanode to cathode area and light intensity were investigated to define the optimum values while the effect of electrolytes, applied cell voltage, membrane, and other operating conditions was controlled. The results showed the optimum ratio of photoanode to

cathode area and light intensity could increase faradaic efficiencies (FE) to 64% for  $\text{HCOO}^-$  and energy efficiencies (EE) to 70% under applied external voltages 1.2 V.

X. Luo et al. [35] developed a 2-dimensional numerical model for PEC  $\text{CO}_2$  utilization that integrated thermodynamics and kinetics of carrier charge with electrochemical for reducing  $\text{CO}_2$  to formic acid in form of  $\text{HCOO}^-$  at the cathode and oxygen evolution at the anode. The PEC flow cell was designed using  $\text{TiO}_2$  on FTO substrates as photoanode, GDE made of carbon paper as cathode, sodium bicarbonate ( $\text{NaHCO}_3$ ) as catholyte, sodium hydroxide ( $\text{NaOH}$ ) as anolyte, and cationic conducting membrane under light intensity,  $I$  ( $100 \text{ mW}\cdot\text{cm}^{-2}$ ). The results showed optimum light intensity could improve the current density of the system, and when the flow rate of  $\text{CO}_2$  was increased, the current density also increases. On the other hand, increasing of  $\text{CO}_2$  flow rate would decrease the conversion efficiency of  $\text{CO}_2$  that relied on optimum operating conditions in the system. Thus, PEC cell configuration design is still a challenge for improving the performance of PEC  $\text{CO}_2$  RR.

S. Castro et al. [85] demonstrated by applying n-type  $\text{TiO}_2$  photoanode coupled with Cu dark cathode to produce  $\text{CH}_3\text{OH}$  and  $\text{CH}_5\text{OH}$  through membrane electrode assembly (MEA) flow cell. Under operating conditions of UV LED light illumination ( $100 \text{ mW}\cdot\text{cm}^{-2}$ ) to photoanode,  $\text{CO}_2$  was circulated using a pump passing through 0.1 M KOH for saturation before being fed to the cathode channel while the same electrolyte was circulated to the anode section.  $\text{TiO}_2$  is widely used as an n-type semiconductor due to the appropriate bandgap that can provide light adsorption in the range of ultraviolet (UV).  $\text{TiO}_2$  is a less expensive and environmentally friendly material. In addition, Cu was reviewed as the high-performance catalyst for hydrocarbon and alcohol production. The results showed the maximum production rate, faradaic efficiency, and energy efficiency of  $\text{CH}_3\text{OH}$  equaled  $9.5 \times 10^{-6} \text{ mol/m}^2\text{s}$ , 16.2%, and 5.2%, respectively. And the maximum production rate, faradaic efficiency, and energy efficiency of  $\text{CH}_5\text{OH}$  equaled  $6.8 \times 10^{-6} \text{ mol/m}^2\text{s}$ , 23.2%, and 6.8%, respectively.

## Chapter 3

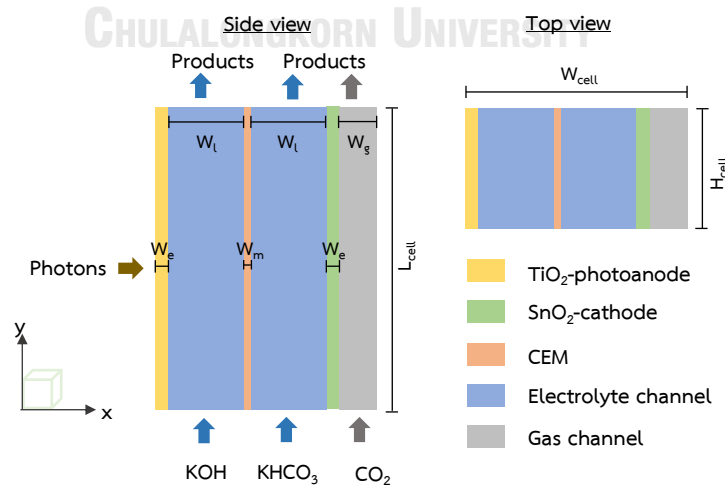

### METHODOLOGY

#### 3.1 Model description of PEC cell for CO<sub>2</sub> RR

To evaluate the effectiveness of the geometric configuration of the PEC cell for CO<sub>2</sub> RR, the COMSOL Multiphysics (5.6) is used to simulate the different configurations of PEC cells. The main components of the PEC cell with specified geometry are designed and rearranged as below.

##### 3.1.1 Microfluidic flow cell (MFC)

The MFC is designed for CO<sub>2</sub> RR. CO<sub>2</sub> in the gas phase is directly fed to SnO<sub>2</sub>-cathode through the inlet of the gas feed channel while 0.5 M KOH and 0.5 M KHCO<sub>3</sub> are used as anolyte and catholyte which are fed to the inlet of the electrolyte channels. The inlet of electrolyte and gas flow channel are placed from the bottom to the top along the length of the cell in y-direction. The MFC is simulated using COMSOL Multiphysics (5.6) with a stationary initialization study using a finite element numerical simulation model to simulate the behavior of MFC. As shown in figure 20, the 2-dimensional model of the MFC cell can be divided into 6 domains from left to right along the width of the cell in x-direction including TiO<sub>2</sub>-photoanode, anolyte channel, PEM, catholyte channel, SnO<sub>2</sub>-cathode, and gas channel, respectively.

**Figure 20.** Schematic diagram of the microfluidic flow cell (MFC) for CO<sub>2</sub> RR.

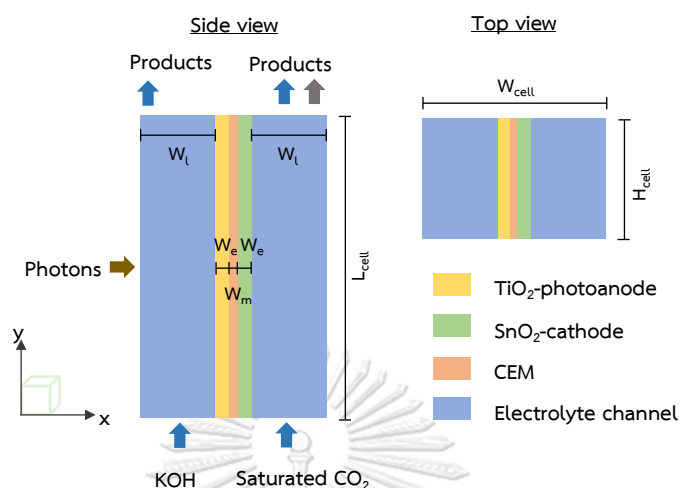

The flow rate of reactants is assumed to be in the range of the laminar regime.  $\text{CO}_2$  in the gas phase is assumed as a weakly compressible fluid while liquid electrolyte is assumed as an incompressible fluid. In addition,  $\text{TiO}_2$  is used as a photocatalyst for a back illumination at the photoanode,  $\text{SnO}_2$  is used as an electrocatalyst for  $\text{CO}_2$  RR at the cathode, and Nafion 117 is used as a product separator to transfer  $\text{H}^+$  from the anodic compartment to the cathodic compartment. Also, the  $\text{CO}_2$  RR and OER will occur at the interface of the deposited catalyst on cathode/electrolyte and the deposited photocatalyst on anode/electrolyte, respectively. Thus, a constant flux photocurrent density is consumed to drive the reaction. The transport of concentrated species and Brinkman's equation are used to simulate the transportation of gas species in GDE. Tertiary current distribution (TCD) is used to analyze the kinetics of all charge species on the photoanode, cathode, and in electrolyte, while Secondary current distribution (SCD) is used for the PEM. To maintain the species flux of reactants and continuity of reactions, Danckwert's boundary condition is provided at the inlets of the cell. Moreover, Nernst Plank's equation and Butler-Volmer's equation are applied to simulate electric charge transport in the cell and reaction behavior on the interface electrode/electrolyte.

### 3.1.2 Membrane electrode assembly flow cell (MEAFC)

The MEAFC is designed for  $\text{CO}_2$  RR.  $\text{CO}_2$  in the gas phase is saturated in the catholyte of 0.5 M  $\text{KHCO}_3$  and is fed to the inlet of the catholyte channel and circulated to avoid bubble formation using a pump. And 0.5 M KOH is used as an anolyte. The inlets of anolyte and catholyte channels are placed from the bottom to the top along the length of the cell in y-direction. Similarly, the MEAFC is simulated using COMSOL Multiphysics (5.6) with a stationary initialization study using a finite element numerical simulation model to simulate the behavior of MEAFC. As shown in figure 21, the 2-dimensional model of the MEAFC cell can be divided into 5 domains from left to right along the width of the cell in x-direction, including anolyte

channel,  $\text{TiO}_2$ -photoanode, PEM,  $\text{SnO}_2$ -cathode, catholyte channel, and gas channel, respectively.

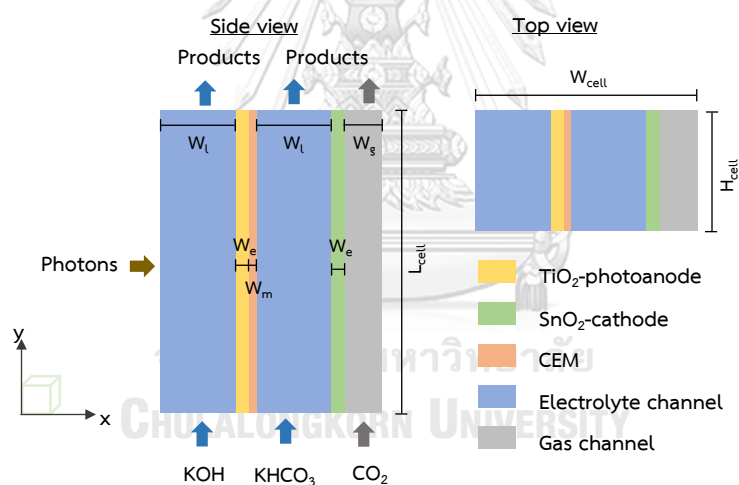

**Figure 21.** Schematic diagram of the membrane electrode assembly flow cell (MEAFC) for  $\text{CO}_2$  RR.

The flow rate of reactants is assumed to be in the range of the laminar regime.  $\text{CO}_2$  in the saturated phase and liquid electrolyte are assumed as an incompressible fluid. In addition,  $\text{TiO}_2$  is used as a photocatalyst for a back illumination at the photoanode,  $\text{SnO}_2$  is used as an electrocatalyst for  $\text{CO}_2$  RR at the cathode, and Nafion 117 is used as a product separator to transfer  $\text{H}^+$  from the anodic to the cathodic compartment. Also, the  $\text{CO}_2$  RR and OER will occur at the interface of deposited catalyst on cathode/electrolyte and deposited photocatalyst on anode/electrolyte, respectively. A constant flux photocurrent density is consumed to drive the reaction. Tertiary current distribution (TCD) is used to analyze the kinetics of all charge species on the photoanode, cathode, and in electrolyte, while Secondary current distribution (SCD) is used for the PEM. To maintain the species flux of reactants and continuity of reactions, Danckwert's boundary condition is provided at the inlets of the cell. Moreover, Nernst Plank's equation and Butler-Volmer's equation are applied to simulate electric charge transport in the cell and reaction behavior on the interface electrode/electrolyte.

### 3.1.3 Microfluid flow cell (MFC) with a zero-gap anode

The MFC with a zero-gap anode is designed for CO<sub>2</sub> RR. CO<sub>2</sub> in the gas phase is directly fed to SnO<sub>2</sub>-cathode through the inlet of the gas feed channel. 0.5 M KOH and 0.5 M KHCO<sub>3</sub>, are used as anolyte and catholyte which are fed to the inlet of the electrolyte channels. The inlet of electrolyte and gas flow channel are placed from the bottom to the top along the length of the cell in y-direction. The MFC with a zero-gap anode is simulated using COMSOL Multiphysics (5.6) with a stationary initialization study using a finite element numerical simulation model to simulate the behavior of MFC with a zero-gap anode. As shown in figure 22, the 2-dimensional model of the MFC cell can be divided into 6 domains from left to right along the width of the cell in x-direction including anolyte channel, TiO<sub>2</sub>-photoanode, PEM, catholyte channel, SnO<sub>2</sub>-cathode, and gas channel, respectively.

**Figure 22.** Schematic diagram of the microfluidic flow cell (MFC) with a zero-gap anode for CO<sub>2</sub> RR.

The flow rate of reactants is assumed to be in the range of the laminar regime. CO<sub>2</sub> in the gas phase is assumed as a weakly compressible fluid while liquid electrolyte is assumed as an incompressible fluid. In addition, TiO<sub>2</sub> is used as a photocatalyst for a back illumination at the photoanode, SnO<sub>2</sub> is used as an electrocatalyst for CO<sub>2</sub> RR at the cathode, and Nafion 117 is used as a product separator to transfer H<sup>+</sup> from the anodic to the cathodic compartment. Also, the CO<sub>2</sub>

RR and OER will occur at the interface of deposited catalyst on cathode/electrolyte and deposited photocatalyst on anode/electrolyte, respectively. A constant flux photocurrent density is consumed to drive the reaction. The transport of concentrated species and Brinkman's equation are used to simulate the transportation of gas species in GDE. Tertiary current distribution (TCD) is used to analyze the kinetics of all charge species on the photoanode, cathode, and electrolyte, while Secondary current distribution (SCD) is used for the PEM. To maintain the species flux of reactants and continuity of reactions, Danckwert's boundary condition is provided at the inlets of the cell. Moreover, Nernst Plank's equation and Butler-Volmer's equation are applied to simulate electric charge transport in the cell and reaction behavior on the interface electrode/electrolyte.

### 3.2 Photoelectrochemical reactions

The PEC CO<sub>2</sub> RR is simulated through COMSOL Multiphysics (5.6) including the reactions at the interface of photoanode/anolyte, the interface of cathode/catholyte, and electrolyte compartments.

#### 3.2.1 Half-cell reactions at the photoanode

##### 1. Light absorption

For this system, the light absorption has larger energy than the bandgap of TiO<sub>2</sub>-photoanode (3.0-3.2 eV) and is sufficient for electric species transportation to generate electron (e<sup>-</sup>) and hole (h<sup>+</sup>) pairs at the photoanode as shown in reaction (18).

##### 2. Oxygen evolution reaction (OER)

Simultaneously, the oxygen gas (O<sub>2</sub>) and water (H<sub>2</sub>O) were formed on the interface of photoanode/anolyte with the electrode potential (E<sup>0</sup>) equal to 0.82 V (referred to SHE). The OER is shown as reaction (19).

### 3.2.2 Half-cell reactions at the cathode

#### 1. CO<sub>2</sub> RR

The reactions (20) and (21) show the formation of HCOO<sup>-</sup> and CO because of multi-electron consumption of CO<sub>2</sub> RR at the interface of cathode/catholyte with E<sup>0</sup> equal to -0.43 V and -0.53 V vs SHE, respectively.

#### 2. Hydrogen evolution reaction (HER)

The hydrogen gas (H<sub>2</sub>) is the product from HER at the interface of cathode/catholyte with E<sup>0</sup> equal to -0.41 V vs SHE that can decrease the faradaic efficiency and current density of HCOO<sup>-</sup> and CO formation. H<sub>2</sub> formation is shown as reaction (22).

### 3.2.3 Dissolution of the CO<sub>2</sub> in the aqueous electrolyte

Apart from the reactions on the electrode surface, the equilibrium reactions and rate constants of KHCO<sub>3</sub> and KOH dissociation are shown in reactions (23) to (28).

### 3.3 Model assumptions

The main assumptions are identified to support the physics model simulation as follows:

1. The main physics model simulation for the PEC cell is at steady-state condition. In contrast, only a few time-dependent (transient) conditions are used for comparison purposes.
2. The system is isothermal. The temperature variation across the PEC cell is relatively low because of the flowing of liquid electrolytes which is a good thermal conductor.
3. The variations across the cell height are negligible to simplify the model. The 2-dimensional model is sufficient.
4. The current collectors are treated as the interfaces between the electrode and electrolyte that occurred electrochemical reactions. Therefore, the ohmic loss across the current collectors is insignificant.
5. Butler Volmer equation is applied to describe the rate of electrochemical reactions.
6. A laminar flow regime is used for fluid flow with controlled velocity. Flow in the gas channel is weakly compressible and the flow in the electrolyte channel is incompressible.
7. The effect of bubble formation is insignificant due to the short simulation time. The effective crossover flux of gas species ( $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{H}_2$ ,  $\text{O}_2$ , and  $\text{N}_2$ ) at the electrochemical interfaces is negligible.
8. The GDEs are treated as homogeneous porous media of the gas diffusion layers (GDLs) and the catalyst layers (CLs). Thus, the average porosity and permeability are used to simulate.

### 3.4 Modeling equations

The governing equations are applied in each domain to simulate mass balance and transportation of species, and electrochemical kinetics of ionic charge species from CO<sub>2</sub> RR in PEC cell. In section 3.4, the modeling equations and input parameters are presented.

#### 3.4.1 Photocurrent density

To decrease the electrical energy consumption for CO<sub>2</sub> utilization, solar energy is provided in which the calculation of photocurrent density has calculated based on the correlation with a wavelength of absorbed light, as expressed in Eq. (6).

$$i = q \int_{\lambda_1}^{\lambda_2} \frac{L\lambda}{hc} d\lambda \quad \text{Eq. (6)}$$

where  $i$  is the incident photocurrent density (A/m<sup>2</sup>)

$q$  is elementary charge ( $1.6022 \times 10^{-19}$  C)

$\lambda$  is the wavelength of absorbed light (m)

$h$  is Planck's constant ( $6.626 \times 10^{-34}$  m<sup>2</sup>·kg/s)

$c$  is light velocity ( $2.998 \times 10^8$  m/s)

$L$  is light transmission loss through the reactor materials

The correlation between the average electrode power density, electric potential, and current density is described in Eq. (7) which is integrated over the boundary to set at the interface between the electrode and the current collector.

$$\int (\phi_s - \phi_{s,ground})(i \cdot n) dS = P_{avg} A \quad \text{Eq. (7)}$$

where  $P_{avg}$  is the average power density (W/m<sup>2</sup>)

$A$  is the boundary area

$\phi_s$  is the electric potential (V)

$\phi_{s,ground}$  is the ground potential of the cell (V)

$i$  is the current density vector (A/m<sup>2</sup>)

$n$  is the normal vector of the boundary pointing into the domain

Note that the boundary electric potential,  $\phi_{s,bnd}$  is set as an initial value to support during the discharge of a PEC cell which provides a maximum power level. The decreasing of output power will occur when the power level over increasing of current which leads to a loss more voltage.

### 3.4.2 Fluid flow

The continuity equation and Navier-Stokes equations are used to express the mass conservation and species transport of momentum, respectively. The system is assumed to be isothermal and a steady state.

#### 1. Gas channel

The physics models for fluid motion in gas channel include laminar flow and transport of concentrated species. The gas is assumed to be a weakly compressible fluid. The overall mass and momentum conservation equations are expressed by Eq. (8) and (9).

$$\nabla \cdot (\rho_g \mathbf{u}_g) = 0 \quad \text{Eq. (8)}$$

$$\rho_g \mathbf{u}_g \cdot \nabla \mathbf{u}_g = \rho_g \mathbf{g} - \nabla p_g + \nabla \cdot (\mu_g (\nabla \mathbf{u}_g + (\nabla \mathbf{u}_g)^T)) - \frac{2}{3} \mu_g (\nabla \cdot \mathbf{u}_g) \mathbf{I} \quad \text{Eq. (9)}$$

where  $p_g$  is the gas pressure (Pa)

$\rho_g$  is the gas density ( $\text{kg} \cdot \text{m}^{-3}$ )

$\mathbf{u}_g$  is the velocity vector ( $\text{m} \cdot \text{s}^{-1}$ )

$\mu_g$  is dynamic gas viscosity ( $\text{kg} \cdot \text{m}^{-1} \cdot \text{s}^{-1}$ )

$\mathbf{g}$  is gravitational acceleration ( $\text{m}^2 \cdot \text{s}^{-1}$ )

$\mathbf{I}$  is the identity tensor

Transport of concentration species consisting of  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{H}_2$ ,  $\text{H}_2\text{O}$  and  $\text{N}_2$  for cathode gas and  $\text{O}_2$ ,  $\text{H}_2\text{O}$  and  $\text{N}_2$  for anode gas. The Maxwell-Stefan equation is applied to define total mass flux species in mass conservation equation are expressed by Eq. (10) and (11).

$$\nabla \cdot \mathbf{n}_{i,g} = 0 \quad \text{Eq. (10)}$$

$$\mathbf{n}_{i,g} = -\rho_g \omega_i \sum_{j=1}^N D_{ij} \left[ \frac{M_g}{M_i} \left( \nabla \omega_j + \omega_j \frac{\nabla M_g}{M_g} \right) + (x_j - \omega_j) \frac{\nabla p_g}{p_g} \right] + \rho_g \mathbf{u}_g \omega_i \quad \text{Eq. (11)}$$

where  $\mathbf{n}_i$  is the total mass flux of gas species

$\omega_i$  is the mass fraction

$x_j$  is the molar fraction

$M_g$  is molar mass of gas mixture

$D_{ij}$  is the diffusion coefficient ( $\text{m}^2 \cdot \text{s}^{-1}$ )

The molar mass of gas mixture,  $M_g$  is defined as the sum of molar mass of gases in the system, as shown in Eq (12).

$$M_g = x_{CO_2} M_{CO_2} + x_{CO} M_{CO} + x_{H_2} M_{H_2} + x_{H_2O} M_{H_2O} + x_{N_2} M_{N_2} \quad \text{Eq. (12)}$$

The diffusion coefficient of multicomponent can be determined using the correlation of Fuller, Schettler, and Giddings, as shown in Eq (13).

$$D_{ij} = \frac{10^{-3} T^{1.75} \left( \frac{1}{M_i} + \frac{1}{M_j} \right)^{1/2}}{p (v_i^{1/3} + v_j^{1/3})} \quad \text{Eq. (13)}$$

where  $D_{ij}$  is multicomponent diffusion coefficient ( $\text{cm}^2 \cdot \text{s}^{-1}$ )

$T$  is temperature (K)

$p$  is the pressure (atm)

$v_i$  is the diffusion volume for molecule i

$M_i$  is molecular weight of gas i ( $\text{g} \cdot \text{mol}^{-1}$ )

## 2. Gas diffusion electrode (GDE)

The physics models for reacting flow in GDE include Brinkman's equation and transport of concentrated species in porous media. The gas is assumed to be a

weakly compressible fluid, the continuity of mass and momentum balance equations are expressed by Eq. (14) and (15).

$$\nabla \cdot (\rho_g u_g) = Q \quad \text{Eq. (14)}$$

$$\begin{aligned} \rho_g u_g \cdot \nabla u_g = \rho_g g - \nabla p_g + \nabla \cdot \left[ \frac{1}{\varepsilon} (\mu_g (\nabla u_g + (\nabla u_g)^\tau) \right. \\ \left. - \frac{2}{3} \mu_g (\nabla \cdot u_g) I) \right] - \left( \frac{\mu_g}{\kappa} \right) u_g \end{aligned} \quad \text{Eq. (15)}$$

where  $Q$  is the mass source term which presents in occurred electrochemical reaction position.

$\varepsilon$  is porosity of GDE

$\tau$  is tortuosity

$\kappa$  is permeability of the GDL or catalyst layer ( $\text{m}^2$ ).

For the continuity mass flux species, the equations are expressed by Eq. (16) and (17).

$$\nabla \cdot n_{i,g} = R_{i,g} \quad \text{Eq. (16)}$$

$$\begin{aligned} n_{i,g} = -\rho_g \omega_i \sum_{j=1}^N D_{ij}^{eff} \left[ \frac{M_g}{M_i} \left( \nabla \omega_j + \omega_j \frac{\nabla M_g}{M_g} \right) + \right. \\ \left. (x_j - \omega_j) \frac{\nabla p_g}{p_g} \right] + \rho_g u_g \omega_i \end{aligned} \quad \text{Eq. (17)}$$

where  $R_i$  is the reaction rate of gas species

$D_{ij}^{eff}$  is the effective gas diffusion coefficient ( $\text{m}^2 \cdot \text{s}^{-1}$ )

The effective gas diffusion coefficient of multicomponent can be determined using the Bruggeman correction is shown in Eq (18).

$$D_{ij}^{eff} = \varepsilon^{1.5} D_{ij} \quad \text{Eq. (18)}$$

### 3. Electrolyte channel

For liquid electrolytes, the motion of incompressible fluid with laminar flow in electrolyte channel. The overall mass and momentum conservation equations are expressed by Eq. (19) and (20).

$$\rho_l \nabla \cdot \mathbf{u}_l = 0 \quad \text{Eq. (19)}$$

$$\rho_l (\mathbf{u}_l \cdot \nabla) \mathbf{u}_l = \rho_l \mathbf{g} - \nabla p_l I + \nabla \cdot (\mu_l (\nabla \mathbf{u}_l + (\nabla \mathbf{u}_l)^T)) \quad \text{Eq. (20)}$$

where  $p_l$  is the liquid electrolyte pressure (Pa)

$\rho_l$  is the gas density ( $\text{kg}\cdot\text{m}^{-3}$ )

$\mathbf{u}_l$  is the velocity vector ( $\text{m}\cdot\text{s}^{-1}$ )

$\mu_l$  is dynamic gas viscosity ( $\text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$ )

To control the flow regime of fluid to be laminar flow, the inlet of fluid velocity is identified from the Reynold numbers ( $Re$ ) given by Eq. (21).

$$\mathbf{u} = \frac{\mu Re}{\rho L} \quad \text{Eq. (21)}$$

where  $\mathbf{u}$  is fluid velocity ( $\text{m}\cdot\text{s}^{-1}$ )

$\mu$  is dynamic fluid viscosity ( $\text{kg}\cdot\text{m}^{-1}\cdot\text{s}^{-1}$ )

$Re$  is Reynold numbers ( $Re < 2000$ )

$L$  is characteristic length (m)

$\rho$  is fluid density ( $\text{kg}\cdot\text{m}^{-3}$ )

#### 3.4.3 Charge transport/ Ionic migration

The mass transport of the dissolved species in the electrolyte or a component in a gas mixture is balanced as shown in Eq. (22).

$$\nabla \cdot \mathbf{n}_i = R_i \quad \text{Eq. (22)}$$

where  $\mathbf{n}_i$  is the total mass flux of ionic species ( $\text{mol}/\text{m}^2\cdot\text{s}$ )

$R_i$  is the term of reaction source/sink of ionic species

The Nernst-Planck equation is applied to examine species transport in terms of diffusion, electric charge migration, and convection, as shown in Eq. (23).

$$n_i = -D_i \nabla c_i - z_i u_{mi} F c_i \nabla \phi_{l,e} + u c_i \quad \text{Eq. (23)}$$

The dissolved species in the electrolyte consist of  $\text{CO}_2$ ,  $\text{K}^+$ ,  $\text{HCO}_3^-$ ,  $\text{H}^+$ ,  $\text{OH}^-$ ,  $\text{CO}_3^{2-}$ ,  $\text{HCOO}^-$ ,  $\text{CO}$ ,  $\text{H}_2$  and  $\text{O}_2$ .

where  $D_i$  is diffusion coefficient of dissolved species ( $\text{m}^2 \cdot \text{s}^{-1}$ )

$c_i$  is species concentration ( $\text{mol} \cdot \text{m}^{-3}$ )

$z_i$  is charge number of dissolved species

$u_{mi}$  is species mobility of dissolved species ( $\text{m}^2 \cdot \text{V}^{-1} \cdot \text{s}^{-1}$ )

$F$  is Faraday's constant ( $96485 \text{ Coulomb} \cdot \text{mol}^{-1}$ )

$\phi_{l,e}$  is electrolyte potential (V)

Faraday's law and Ohm's law were applied to identify the charge balance in the electrolyte channel, as shown in Eq. (24).

$$i_{l,e} = F \sum_i z_i R_i \quad \text{Eq. (24)}$$

Due to the charge conservation as Eq. (25), the current of the electrolyte is provided by Ohm's law, as shown in Eq. (26):

$$\nabla \cdot i_{l,e} = 0 \quad \text{Eq. (25)}$$

$$i_{l,e} = F \sum_i z_i (-D_i \nabla c_i - z_i u_{mi} F c_i \nabla \phi_{l,e}) \quad \text{Eq. (26)}$$

where  $i_{l,e}$  is the current density in the electrolyte ( $\text{A} \cdot \text{m}^{-2}$ )

In the electrolyte channels, the electroneutrality condition is applied as described by the following Eq. (27).

$$\sum_i z_i c_i = 0 \quad \text{Eq. (27)}$$

In the membrane,  $\text{H}^+$  is transferred from the anode to the cathode compartment while the negative ions concentration is set as constant. Thus, the species flux of electroneutrality and electric conductivity in the membrane are expressed as Eq. (28) and (29).

$$n_{\text{H}^+} = -z_i u_{mi} F c_i \nabla \phi_{l,m} \quad \text{Eq. (28)}$$

$$i_{l,m} = -\sigma_{l,m} \nabla \phi_{l,e} \quad \text{Eq. (29)}$$

where  $i_{l,m}$  is the current density in the membrane ( $A \cdot m^{-2}$ )

$\sigma_{l,m}$  is ionic conductivity of membrane ( $S \cdot m^{-1}$ )

For the electrodes, a gas mixture is transported by diffusion and convection by following Eq. (30) and (31) in the cathode and anode, respectively.

$$n_i = -\rho D \nabla \omega_i + \rho u \omega_i \quad \text{Eq. (30)}$$

$$n_i = -\rho D \nabla \omega_i \quad \text{Eq. (31)}$$

Note that the gas species at the cathode and the anode consist of  $CO_2$ ,  $CO$ ,  $H_2$ ,  $H_2O$ , and  $O_2$ .

And the current density at the electrodes is imposed by Ohm's law, as shown in Eq. (32).

$$i_s = -\sigma_s \nabla \phi_s \quad \text{Eq. (32)}$$

where  $i_s$  is the current density at the electrodes ( $A \cdot m^{-2}$ )

$\sigma_s$  is electronic conductivity of electrodes ( $S \cdot m^{-1}$ )

#### 3.4.4 Electrochemical kinetics

The kinetics of electrochemical reaction could be expressed using the Butler-Volmer equation. The local current density of products ( $i_{local}$ ) from  $CO_2$  RR is given by Eq. (33).

$$i_i = k_i \left[ c_R \exp\left(\frac{\alpha_a F \eta}{RT}\right) - c_O \exp\left(\frac{-\alpha_c F \eta}{RT}\right) \right] \quad \text{Eq. (33)}$$

where  $i_i$  is the local charge transfer current density for the reaction ( $A \cdot m^{-2}$ )

$k_i$  is the kinetic pre-exponential parameter for specific reaction

$c_R$  is reduced species expression

$c_O$  is oxidized species expression

$\alpha_a$  is anodic charge transfer coefficient

$\alpha_c$  is cathodic charge transfer coefficient

$R$  is the gas constant ( $8.314 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$ )

$T$  is the operating temperature (K)

$\eta$  is the overpotential (V)

The kinetic pre-exponential parameter ( $k_i$ ) is obtained from laboratory experiment set up where  $k_i$  can be presented by a reference exchange current density for specific reaction ( $i_i^{ref}$ ). In addition, due to the rate reactions of CO<sub>2</sub> RR in reactions (20) and (21) at the cathode, local concentration of CO<sub>2</sub> and C<sub>R</sub> is defined to be 0. The current densities transport of HCOO<sup>-</sup> and CO are given by following Eq. (34) and (35).

$$i_{HCOO^-} = i_{HCOO^-}^{ref} \frac{C_{CO_2}}{C_{CO_2,ref}} \exp\left(-\frac{2\alpha_{HCOO^-}F}{RT} \eta_{HCOO^-}\right) \quad \text{Eq. (34)}$$

$$i_{CO} = i_{CO}^{ref} \frac{C_{CO_2}}{C_{CO_2,ref}} \exp\left(-\frac{2\alpha_{CO}F}{RT} \eta_{CO}\right) \quad \text{Eq. (35)}$$

where  $C_{CO_2}$  is the CO<sub>2</sub> concentrations is to be reduced.

$C_{CO_2,ref}$  is the reference CO<sub>2</sub> concentrations

The reactions (19) and (22) are mass transfer-independent, therefore the current densities of H<sub>2</sub> and O<sub>2</sub> can be written as following Eq. (36) and (37).

$$i_{H_2} = i_{H_2}^{ref} \exp\left(-\frac{2\alpha_{H_2}F}{RT} \eta_{H_2}\right) \quad \text{Eq. (36)}$$

$$i_{O_2} = i_{O_2}^{ref} \exp\left(\frac{2\alpha_{O_2}F}{RT} \eta_{O_2}\right) \quad \text{Eq. (37)}$$

The overpotential ( $\eta$ ) of the species is given in correlation with cell voltage as Eq. (38) or (39).

$$V_{cell} = (E_a^0 - E_c^0) + (\eta_a + \eta_c) + \eta_{ohm} \quad \text{Eq. (38)}$$

$$\eta = \phi_s - \phi_l - \phi_0 \quad \text{Eq. (39)}$$

where  $V_{cell}$  is cell potential (V)

$E_a^0$  is equilibrium cell potential at anode (V)

$E_c^0$  is equilibrium cell potential at cathode (V)

$\eta_{ohm}$  is ohmic drop

$\eta_a$  is anodic overpotential

$\eta_c$  is cathodic overpotential

$\phi_s$  is electric potential (V)

$\phi_l$  is electrolyte potential (V)

$\phi_0$  is equilibrium potential (V)

Therefore, the rate of electrochemical reactions at the interface of electrodes expressed as  $R_i$  is shown in Eq. (40).

$$R_i = \frac{\nu_i i_i}{n_{i,e} F} \quad \text{Eq. (40)}$$

where  $\nu_i$  is the stoichiometric coefficient of the species  $i$  in the reaction

$n_{i,e}$  is the number of the electrons

## Chapter 4

### RESULTS AND DISCUSSION

The behavior of the PEC CO<sub>2</sub> RR is simulated using the physics model described in the previous section. Apart from isothermal and steady-state conditions, the simulation of time-dependent (transient) conditions was applied to compare the efficiencies of different PEC CO<sub>2</sub> RR systems. Many factors were identified to derive the excellent efficiency of PEC CO<sub>2</sub> RR for scaling up CO<sub>2</sub> RR in industrial production. Consequently, this study aims to evaluate some of the variables affecting PEC cells for CO<sub>2</sub> RR to derive the optimum performance.

#### 4.1 Physics model validation

Prior simulation, the physics model should be validated to achieve the simulation of electrochemical CO<sub>2</sub> RR with high accuracy. The reducing discrepancy of the faradaic efficiency of HCOO<sup>-</sup> (FE<sub>HCOO<sup>-</sup></sub>) between the experiment and physics model was performed by setting the controlled variables similarly. For example, cell configuration, operating temperature and pressure, pH of electrolytes, and the ratio of gas to liquid feeding (G/L). The accuracy of the physics model for electrochemical simulation was investigated following the correlation of FE and absolute cell voltage  $|E_{\text{cell}}|$  curve. The FE<sub>HCOO<sup>-</sup></sub> at various  $|E_{\text{cell}}|$  between 1.5 V and 3.5 V, which were obtained from simulation of 2-dimensional MFC configuration, were compared with the experimental data reported in the literature under similar operating conditions as shown in figure 23

**Figure 23.** Comparison between the faradaic efficiencies of CO<sub>2</sub> RR to HCO<sub>3</sub><sup>-</sup> (FE<sub>HCO<sub>3</sub><sup>-</sup></sub>) at various cell voltages, |E<sub>cell</sub>|, between 1.5 V and 3.5 V as predicted from the physics model and experiment data reported in the literature, under similar operating conditions.

Validation of the physics model was actualized by comparing the results performance with the experimental data of I. E. Irem et al. [84], as shown in table 16. For MFC configuration, Sn based GDE cathode was used as a working-electrode operated under non-illuminated condition. The cause of fluctuation in product distribution of CO<sub>2</sub> RR depending on cell voltage can be described through the electrochemical process. When bias voltage applied on anode surface, the electrons would be excited across the energy band gap of the anodic semiconductor. It was found that the bottom of the conduction band (CB) and the top of the valence band (VB) would be possessed by electrons and holes, respectively. The recombination of electrons and holes could reveal on the anode. In contrast, the excited electrons would be transferred to react with CO<sub>2</sub> on the cathode surface while oxidized holes would provide OER on the anode surface when applied energy reached the equilibrium overpotentials.

Figure 23 shows the effect of cell voltage on product distribution of CO<sub>2</sub> RR which was presented by FE<sub>HCO<sub>3</sub><sup>-</sup></sub>. The electrochemical CO<sub>2</sub> reduction on the cathode

surface can be observed when the absolute applied cell voltages are higher than 1.5 V ( $|E_{\text{cell}}| \geq 1.5 \text{ V}$ ). The gradually increasing of  $FE_{\text{HCOO}^-}$  is observed when the low voltages ( $1.5\text{V} \leq |E_{\text{cell}}| \leq 1.8\text{V}$ ) were applied due to activation polarization. The overpotential when applying low voltages was derived from activation energy which is the minimum energy required for a chemical reaction. Consequently, the  $FE_{\text{HCOO}^-}$  disappears at the beginning of the activation polarization, in which activation overpotential was less than the equilibrium potential of  $\text{CO}_2$  RR to  $\text{HCOO}^-$ . Then, the  $FE_{\text{HCOO}^-}$  is simultaneously increased to a maximum value when applied higher voltages ( $1.8\text{V} < |E_{\text{cell}}| \leq 2.8\text{V}$ ) because the energy for absorbed  $\text{CO}_2$  reduction on the cathode to  $\text{HCOO}^-$  was enough. However, the  $FE_{\text{HCOO}^-}$  is slightly decreased when the applied voltages become higher than the maximum point ( $|E_{\text{cell}}| > 2.8\text{V}$ ) because the overpotential for  $\text{CO}_2$  RR is derived by  $\text{CO}_2$  concentration on the cathode surface. The concentration overpotential is the potential gradient between the bulk (diffusion layer) and cathode surface which has different  $\text{CO}_2$  concentrations between two positions. When  $\text{CO}_2$  concentration on the cathode surface decreased,  $FE_{\text{HCOO}^-}$  would be decreased. In addition, the competition of HER would be increased when applied higher voltages.

It can also be seen that, the deviation of  $FE_{\text{HCOO}^-}$  from the physics model against experimental data shows a good agreement. The accuracy of the physics model in predicting the results was examined using the root mean square error (RMSE) which is equal to 3.36%. Therefore, validation of the physics model from COMSOL Multiphysics was confirmed for analysis of the variables affecting PEC cell for  $\text{CO}_2$  RR to  $\text{HCOO}^-$ .

Regarding the activation and concentration polarizations, the ohmic polarization also affected the performance of PEC cell. The ohmic polarization is derived from the resistivity of the components such as ion-exchange membrane, electrolyte, and electrode effects on electric limitation. For this reason, the different

PEC cell configurations were simulated to define the optimum configuration in order to provide a proper environment for CO<sub>2</sub> RR to HCOO<sup>-</sup>.

#### 4.2 Arrangement of PEC cell configuration

To evaluate the effect of the arrangement of PEC cells on cell performance, different PEC cell configurations consisting of MFC, MEAFC, and MFC with a zero-gap anode were simulated under specific controlled variables. As the results of the physics model validation, the cathodic polarization of electrochemical CO<sub>2</sub> RR under dark conditions appeared when cell voltage was applied more than 1.5 V, ( $|E_{\text{cell}}| > 1.5$  V). Then the illuminated simulation on TiO<sub>2</sub> photoanode was controlled under 1.5 V of boundary electric potential initial value,  $\phi_{s,bnd,int}$  and 1.0 mA•cm<sup>-2</sup> of photocurrent density. Formate (HCOO<sup>-</sup>) is a liquid product from CO<sub>2</sub> RR which was concerned with the simulation of PEC cells for CO<sub>2</sub> RR.

**Figure 24.** Concentration of  $\text{HCOO}^-$  on the cathode surface of different PEC cell configurations including (a) MFC, (b) MEAFC, and (c) MFC with a zero-gap anode, with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

The simulation of PEC CO<sub>2</sub> RR using COMSOL Multiphysics in this work mainly applied steady-state condition, while a few time-dependent simulations were required for comparison purposes.

From figure 24, the concentration gradient of HCOO<sup>-</sup>, occurring on the interface between the catholyte channel and cathode GDE, was obtained from different configurations of PEC cells. The initial concentration of HCOO<sup>-</sup> appears on SnO<sub>2</sub>-GDE and tends to decrease at the domain of electrolyte. The HCOO<sup>-</sup> is diminished because the attraction of negative ions and positive ions in an aqueous solution provides the production of HCOOH (formic acid) and HCOOK (potassium formate). Under similar controlled operating conditions, the outlet HCOO<sup>-</sup> concentrations on the interface between the catholyte channel and cathode GDE were 0.36 mol•m<sup>-3</sup>, 0.32 mol•m<sup>-3</sup>, and 1.68 mol•m<sup>-3</sup> obtained from MFC, MEAFC, and MFC with a zero-gap anode, respectively.

The MFC, MEAFC, and MFC with a zero-gap anode were simulated and evaluated the performance through CO<sub>2</sub> conversion ( $X_{CO_2}$ ), product selectivity ( $S$ ), faradaic efficiency (FE%) and energy efficiency (EE%) as shown in figure 25 to 27, respectively.

**Figure 25.** CO<sub>2</sub> conversion,  $X_{CO_2}$ , of different PEC cells configurations with applied  $\phi_{s,bnd,int}$  at 1.5 V and 1.0 mA•cm<sup>-2</sup> photocurrent density on the TiO<sub>2</sub> photoanode.

From figure 25,  $X_{CO_2}$  derived from direct gaseous  $CO_2$  feeding should be higher than that of the dissolved  $CO_2$  feeding because of the limitation of mass transfer. However, the highest 0.23 of  $X_{CO_2}$  was obtained from the MEAFC configuration because assumption of the saturated  $CO_2$  in  $KHCO_3$  solution could supply the maximum dissolved  $CO_2$  under the condition at which the solution exists. Thus, the initial concentrations for saturated  $CO_2$  in 0.5 M  $KHCO_3$  were set to be in instant equilibrium. In contrast, the low value of  $X_{CO_2}$  derived from MFC and MFC with zero-gap anode configurations were calculated from simulation results of transportation of gaseous  $CO_2$  through a porous media. Besides, the adding concentration of  $CO_2$  for gas phase diffusion resulted in decreasing overall conversion. For this study, only a few seconds were simulated due to the limitation of memory requirement, thus, the residence time was too short to convert  $CO_2$ . The comparison of  $X_{CO_2}$  from different PEC cell configurations with different fed positions cannot be concluded. Therefore, the other indicators were presented to evaluate the cell performance.

**Figure 26.** Product selectivity,  $S$ , obtained from different PEC cells configurations with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $TiO_2$  photoanode.

$S_{\text{HCOO}^-}$  derived from the MFC and MFC with zero-gap anode configurations are higher than  $S_{\text{HCOO}^-}$  derived from the MEA configuration as shown in figure 26. The feeding of gaseous  $\text{CO}_2$  could solve the limitation of mass transfer. Although  $X_{\text{CO}_2}$  derived from MEAFC configuration is high, the  $S_{\text{HCOO}^-}$  derived from MEAFC configuration is low due to the competition of other reduced species, especially 0.54 of  $S_{\text{H}_2}$  and 0.06 of  $S_{\text{CO}}$ . The 0.62 of  $S_{\text{HCOO}^-}$  derived from MFC with a zero-gap anode is higher than that of MFC due to low resistance between two electrodes, which causes enough overpotential for activating the electrochemical reactions.

**Figure 27.** FE (%) and EE (%) of different PEC cells configurations with applied  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

From figure 27, the highest  $\text{FE}_{\text{HCOO}^-}$  of 68.6% was obtained from the MFC with zero-gap anode configuration because it was designed to overcome the limitation of mass transfer and ohmic overpotential loss by integrating half-cell of the MFC and MEAFC configurations. The half-cell of MFC configuration is applied on the cathodic compartment to increase  $\text{CO}_2$  concentration, while the half-cell of the MEAFC configuration is applied on the anodic to reduce ohmic loss. The  $\text{FE}_{\text{HCOO}^-}$  of 58.1% and 44.9% obtained from the MFC and MEAFC are lower than that of the MFC with a zero-gap anode due to the fact that the ohmic polarization or potential drop

occurs as a result of product reduction performed from film covering on the cathode surface.

The  $EE_{\text{HCOO}^-}$  is the ratio of thermoneutral energy to applied energy of FE%, hence, EE% is directly proportional to FE%. The  $EE_{\text{HCOO}^-}$  of MFC, MEAFC, and MFC with a zero-gap anode were 51.1%, 39.5%, and 60.4%, respectively.

The PEC cell for  $\text{CO}_2$  RR to  $\text{HCOO}^-$  should provide high  $X_{\text{CO}_2}$ , and  $S_{\text{HCOO}^-}$  for saving capital costs as well as high  $FE_{\text{HCOO}^-}$  and  $EE_{\text{HCOO}^-}$  for saving operating cost. Under controlled similarly operating conditions, the MFC with a zero-gap anode configuration was chosen as a PEC cell simulation. Besides, other variables affecting cell performance were also studied to improve the performance of PEC cells.

#### 4.3 Light intensity

To evaluate the effect of energy consumption on cell performance, light intensity ( $\text{mW}\cdot\text{cm}^{-2}$ ) was applied in a form of photocurrent density of 0.1, 0.5, 1.0, 5.0, 10.0, and 15.0  $\text{mA}\cdot\text{cm}^{-2}$  with specific boundary electric potential initial value. The MFC with a zero-gap anode was simulated at various current densities to evaluate the  $X_{\text{CO}_2}$ ,  $S$ , FE%, and EE% as performance indicators.

**Figure 28.**  $\text{CO}_2$  conversion,  $X_{\text{CO}_2}$ , obtained at various applied current densities using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V on the  $\text{TiO}_2$  photoanode.

The overpotential of the working cathode should be directly proportional to the amount of applied current density. The excited electrons derived from the activation of applied bias would be transferred to reduce  $\text{CO}_2$  on the cathode surface. Then, a constant increase of  $X_{\text{CO}_2}$  was demonstrated when higher current densities were applied to  $\text{TiO}_2$ -photoanode as shown in figure 28. From the results, 0.19 of  $X_{\text{CO}_2}$  was achieved when  $15 \text{ mA}\cdot\text{cm}^{-2}$  of current density was applied.

**Figure 29.** Product selectivity,  $S$ , obtained at various applied current densities using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V on the  $\text{TiO}_2$  photoanode.

Figure 29 reveals the product distribution of  $\text{CO}_2$  reduction at various applied current densities. When current densities were applied to  $\text{TiO}_2$ -photoanode enough to activate  $\text{CO}_2$  RR,  $S_{\text{HCOO}^-}$  and  $S_{\text{CO}}$  increased dramatically to the highest value. In contrast,  $S_{\text{H}_2}$  decreased dramatically when  $\text{CO}_2$  RR occurred. Then, the depletion of  $\text{CO}_2$  on the cathode surface caused the competition of HER and decreasing  $\text{CO}_2$  reduction. Therefore, the optimum applied current density required for  $\text{CO}_2$  RR to achieve high  $S_{\text{HCOO}^-}$  was 0.6 when  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  of current density was applied.

The results given above can use to insist on the dependence of  $\text{CO}_2$  concentration on the active interface (three-phase boundary) of reaction kinetics of  $\text{CO}_2$  reduction, as described in mass-dependent equation of Butler-Volmer shown in Eq. (34) and (35). Besides, the reaction kinetics of HER were independent of  $\text{CO}_2$

concentration, as described in mass-independent equation of Butler-Volmer shown in Eq. (36).

$$i_{HCOO^-} = i_{HCOO^-}^{ref} \frac{C_{CO_2}}{C_{CO_2,ref}} \exp\left(-\frac{2\alpha_{HCOO^-}F}{RT} \eta_{HCOO^-}\right) \quad \text{Eq. (34)}$$

$$i_{CO} = i_{CO}^{ref} \frac{C_{CO_2}}{C_{CO_2,ref}} \exp\left(-\frac{2\alpha_{CO}F}{RT} \eta_{CO}\right) \quad \text{Eq. (35)}$$

$$i_{H_2} = i_{H_2}^{ref} \exp\left(-\frac{2\alpha_{H_2}F}{RT} \eta_{H_2}\right) \quad \text{Eq. (36)}$$

**Figure 30.** FE (%) obtained at various applied current densities using MFC with a zero-gap anode with applied  $|E_{cell}|$  at 1.5 V on the TiO<sub>2</sub> photoanode

**Figure 31.** EE (%) obtained at various applied current densities using MFC with a zero-gap anode with applied  $|E_{cell}|$  at 1.5 V on the TiO<sub>2</sub> photoanode.

The FE% can be derived from the amount of energy to drive electrochemical production. However, FE% of the product displays a similar trend as selectivity due to the electrons which are transferred to reduce  $\text{CO}_2$  on the cathode being directly proportional to the applied current density. The EE% is constant with respect to FE% so the deviations of FE%, and EE% from applied various current densities show similar trends in figures 30 and 31. Therefore, when  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  of current density was applied, the highest values of 68.7% of  $\text{FE}_{\text{HCOO}^-}$  and 60.4% of  $\text{EE}_{\text{HCOO}^-}$  were obtained.

#### 4.4 PEC cell length

To evaluate the effect of the surface area of PEC cell on cell performance, PEC cell lengths of 1.0, 1.5, 3.0, 4.0, 6.0, 8.0, and 10.0 cm were varied with specific controlled PEC cell height. The MFC with a zero-gap anode was simulated at various PEC cell lengths to evaluate the  $X_{\text{CO}_2}$ ,  $S$ , FE%, and EE% as performance indicators.

**Figure 32.**  $\text{CO}_2$  conversion,  $X_{\text{CO}_2}$ , obtained at various PEC cell length using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode

From figure 32, the various cell lengths were simulated to observe the effect on  $X_{\text{CO}_2}$ . The results show that the increase  $X_{\text{CO}_2}$  ranged from 0.11 to 0.21 when the cell length was increased from 0.1 cm to 1.0 cm. The increasing cell length can

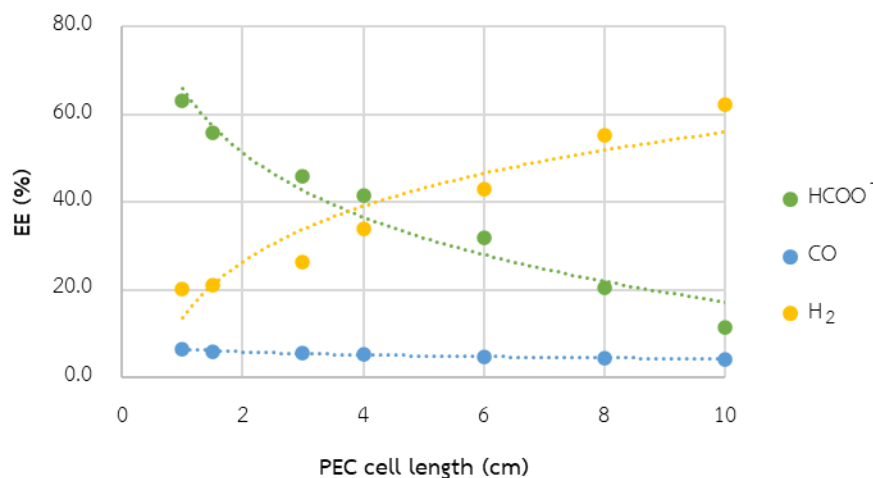

provide a larger surface area to absorb  $\text{CO}_2$  on the electrode surface for electrochemical reactions.

**Figure 33.** Product selectivity,  $S$ , obtained at various PEC cell length using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 34.** FE (%) obtained at various PEC cell length using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 35.** EE (%) obtained at various PEC cell length using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

However, the lack of average  $\text{CO}_2$  concentration could occur when the longer PEC cell was used, resulting in continuous decreasing  $S_{\text{HCOO}^-}$ ,  $\text{FE}_{\text{HCOO}^-}$  and  $\text{EE}_{\text{HCOO}^-}$  as shown in figures 33 to 35, respectively. Another problem is the increase of the HER which can produce  $\text{H}_2$ , regardless the concentration of ion species in the cell. Hence, diminished average  $\text{CO}_2$  concentration and competition of HER would decrease the current density for  $\text{HCOO}^-$  formation which is the cause of decreasing  $S_{\text{HCOO}^-}$ ,  $\text{FE}_{\text{HCOO}^-}$  and  $\text{EE}_{\text{HCOO}^-}$ .

According to above results, the minimum PEC cell length with acceptable  $X_{\text{CO}_2}$  is essential to define for PEC  $\text{CO}_2$  RR simulation. The minimum PEC cell length for this study which still obtains high FE% and EE% for  $\text{HCOO}^-$  production is required. At 1.5 cm of PEC cell length achieved 0.17 of  $X_{\text{CO}_2}$ , 0.57 of  $S_{\text{HCOO}^-}$ , 63.3% of  $\text{FE}_{\text{HCOO}^-}$ , and 55.7% of  $\text{EE}_{\text{HCOO}^-}$ . Thus, the other geometric variables of the PEC cell were studied to guide the scaling-up PEC cell for  $\text{CO}_2$  conversion industry.

#### 4.5 Gas channel width

To evaluate the effect of geometric configuration of the PEC cell on cell performance, gas channel widths of 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0, and 8.0 mm were varied with a specific controlled surface area of the PEC cell. The MFC with a zero-gap anode was simulated at various PEC cell lengths to evaluate  $X_{CO_2}$ ,  $S$ , FE%, and EE% as performance indicators.

**Figure 36.** (a) The flow velocity and (b) mole fraction of  $CO_2$  inside the gas channel with the width,  $W_g$ , of 2 mm, using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $TiO_2$  photoanode.

From figure 36(a), the outlet boundary of the gas channel was set as a fully developed laminar flow to sustain the continuous flow of gas in the channel. The mole fraction of  $CO_2$  inside the gas channel can be used to evaluate the diffusion of  $CO_2$  from the gas channel to the active site on the GDE, as shown in figure 36(b).

**Figure 37.** CO<sub>2</sub> conversion,  $X_{CO_2}$  and inlet gas velocity at various gas channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and 1.0 mA•cm<sup>-2</sup> photocurrent density on the TiO<sub>2</sub> photoanode.

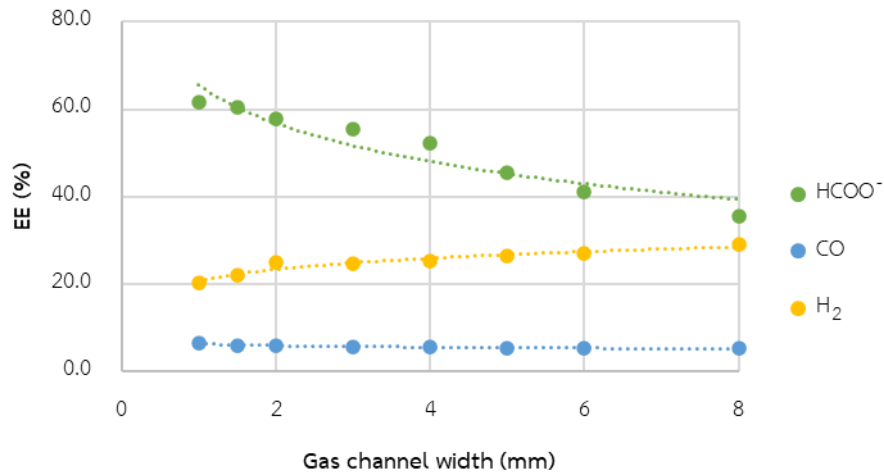

Figure 37 presents the effect of variation of gas channel widths on the inlet gas velocity. When wider gas channels were simulated, the inlet gas velocity was lowered. The decreasing inlet gas velocity provided longer residence time for electrochemical reactions which resulted in an improvement of  $X_{CO_2}$ . For this reason,  $X_{CO_2}$  was increased when wider gas channel was simulated, as shown in figure 37.  $X_{CO_2}$  of 0.24 as obtained when 8 mm of gas channel width was used for simulation.

**Figure 38.** Product selectivity,  $S$ , obtained at various gas channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 39.** FE (%) obtained at various gas channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 40.** EE (%) obtained at various gas channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

From figures 38 to 40, the high value of  $S_{\text{HCOO}^-}$ ,  $\text{FE}_{\text{HCOO}^-}$  and  $\text{EE}_{\text{HCOO}^-}$  were obtained when a narrow gas channel was used for PEC  $\text{CO}_2$  RR. When a narrow gas channel was used, faster inlet gas velocity appeared, which could enhance the  $\text{CO}_2$  concentration on the active surface. Hence, the accumulation of  $\text{CO}_2$  on the active area motivated the increase of current density and rate of reaction. In addition,  $S_{\text{HCOO}^-}$ ,  $\text{FE}_{\text{HCOO}^-}$  and  $\text{EE}_{\text{HCOO}^-}$  tended to decrease when using the wider gas channel, which the diffusion and accumulation of  $\text{CO}_2$  on the active area are low.

However, the reaction kinetics were independent of  $\text{CO}_2$  concentration on the active interface when narrower gas channel was used, which provided very fast inlet gas velocity.

Consequently, the optimum gas channel width for this study is required to achieve high  $S_{\text{HCOO}^-}$ ,  $\text{FE}_{\text{HCOO}^-}$  and  $\text{EE}_{\text{HCOO}^-}$  with acceptable  $X_{\text{CO}_2}$ . Using the gas channel width 1.5 mm achieved 0.17 of  $X_{\text{CO}_2}$ , 0.60 of  $S_{\text{HCOO}^-}$ , 68.7% of  $\text{FE}_{\text{HCOO}^-}$ , and 60.4% of  $\text{EE}_{\text{HCOO}^-}$ . Next, the effects of various electrolyte channel widths were analyzed on PEC cell performance.

#### 4.6 Electrolyte channel width

To evaluate the effect of the geometric configuration of the PEC cell on cell performance, electrolyte channel widths of 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 6.0, and 8.0 mm were varied with a specific controlled surface area of the PEC cell. The MFC with a zero-gap anode was simulated at various electrolyte channel widths to evaluate  $X_{CO_2}$ ,  $S$ , FE%, and EE% as performance indicators.

**Figure 41.** CO<sub>2</sub> conversion,  $X_{CO_2}$ , and inlet electrolyte velocity at various electrolyte channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and 1.0 mA•cm<sup>-2</sup> photocurrent density on the TiO<sub>2</sub> photoanode.

Figure 41 presents the variation of electrolyte channel width effects on the inlet electrolyte velocity. When wider electrolyte channels were simulated, the inlet electrolyte velocity was lowered. Decreasing inlet electrolyte velocity provided longer residence time for electrochemical reactions which resulted in improvement of  $X_{CO_2}$ . For this reason,  $X_{CO_2}$  was increased when wider electrolyte channel was simulated, as shown in figure 41.  $X_{CO_2}$  of 0.21 was obtained when 8.0 mm of electrolyte channel width was used for simulation.

**Figure 42.** Electrolyte potential inside catholyte channel with the width,  $W_c$ , of 2 mm, using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

The rate of electrochemical reaction is given by Eq. (40) derived from the local current density and overpotential which are described in the Butler-Volmer equation as following Eq. (33) and (39).

$$i_i = k_i \left[ c_R \exp\left(\frac{\alpha_a F \eta}{RT}\right) - c_O \exp\left(\frac{-\alpha_c F \eta}{RT}\right) \right] \quad \text{Eq. (33)}$$

$$\eta = \phi_s - \phi_l - \phi_0 \quad \text{Eq. (39)}$$

$$R_i = \frac{v_i i_i}{n_{i,e} F} \quad \text{Eq. (40)}$$

From figure 42, the electrolyte potential ( $\phi_l$ ) inside the catholyte channel decreased along the cell length which was in line with the rate of reaction according to the rate of the electrochemical reactions and are described as a function of the overpotential ( $\eta$ ).

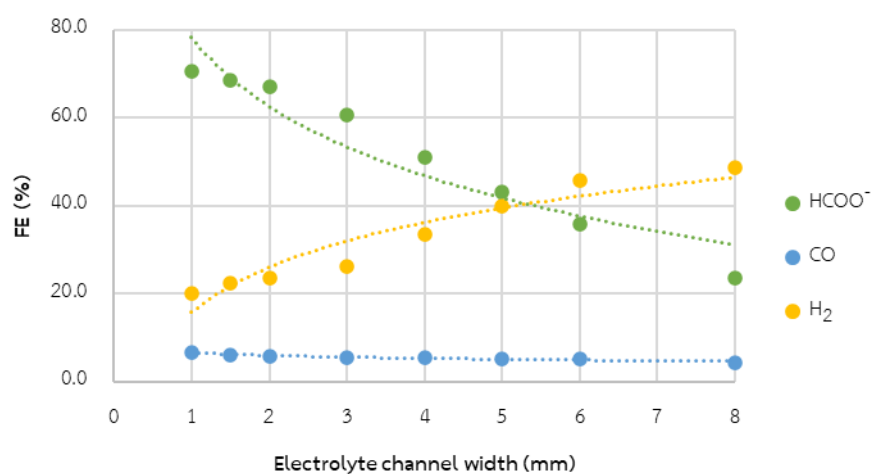

In addition, charge transport which is described in the Nernst-Planck's equation resulted from the diffusion, migration, and convection of ionic species as shown in Eq. (22) and (23). Therefore, the electrolyte width that affects the rate of ionic diffusion also affects the rate of electrochemical reactions.

$$\nabla \cdot n_i = R_i \quad \text{Eq. (22)}$$

$$n_i = -D_i \nabla c_i - z_i u_{mi} F c_i \nabla \phi_{l,e} + u c_i \quad \text{Eq. (23)}$$

**Figure 43.** Product selectivity,  $S$ , obtained at various electrolyte channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $1.0 \text{ mA}\cdot\text{cm}^{-2}$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 44.** FE (%) obtained at various electrolyte channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and  $v$  photocurrent density on the  $\text{TiO}_2$  photoanode.

**Figure 45.** EE (%) obtained at various electrolyte channel widths using MFC with a zero-gap anode with  $\phi_{s,bnd,int}$  at 1.5 V and 1.0 mA•cm<sup>-2</sup> photocurrent density on the TiO<sub>2</sub> photoanode.

From figures 43 to 45, the high values of  $S_{HCOO^-}$ ,  $FE_{HCOO^-}$  and  $EE_{HCOO^-}$  were obtained when a narrow electrolyte channel was used for PEC CO<sub>2</sub> RR. When narrow electrolyte channel was used, faster transport of ionic species appeared which could enhance the rate of electrochemical reaction. The average CO<sub>2</sub> concentration also motivated the increase of partial current density and rate of electrochemical reactions. However,  $S_{HCOO^-}$ ,  $FE_{HCOO^-}$  and  $EE_{HCOO^-}$  tended to decrease when using wider electrolyte channel. Therefore, the H<sub>2</sub> competition increased when using wider electrolyte channel which provided lower transport of ionic species. These results can be concluded that the ohmic loss increased when wider electrolyte channel was used.

Consequently, the maximum electrolyte channel width for this study is required to achieve high  $S_{HCOO^-}$ ,  $FE_{HCOO^-}$  and  $EE_{HCOO^-}$  with acceptable  $X_{CO_2}$ . Using electrolyte channel width of 2.0 mm achieved 0.18 of  $X_{CO_2}$ , 0.59 of  $S_{HCOO^-}$ , 67.0% of  $FE_{HCOO^-}$ , and 59.0% of  $EE_{HCOO^-}$ .

According to the simulation results of PEC cell, it is evident that the arrangement and geometric design of cell components play important roles in the

cell performance. The reasons for performance variation are derived from the overpotential of activation energy,  $\text{CO}_2$  concentration on the active site, and resistivity of each component. Thus, the optimum geometric design of a specific system should be concerned to achieve the maximum performance of the PEC cell.

## Chapter 5

### CONCLUSIONS

#### 5.1 Conclusions

In this study, a simulation of CO<sub>2</sub> utilization was performed through a 2-dimensional PEC cell applying the physics model in COMSOL Multiphysics. The numerical analysis from COMSOL Multiphysics assembled physics models which included tertiary current distribution (TCD), secondary current distribution (SCD), laminar flow, and transport of concentrated species in porous media described the behavior of the PEC process for CO<sub>2</sub> RR to CO and HCOO<sup>-</sup>.

Besides, the aim is to evaluate the affecting variables of PEC cells through physics model simulation; thus, a steady-state and a few time-dependent conditions were simulated. After the simulation of specific systems, it was found that the results of the present study can be concluded as follows:

1. MEAFC configuration provides the value of  $X_{CO_2}$  higher than that of MFC and MFC with zero-gap anode configurations because the MEAFC feeding is a reactant in form of saturated CO<sub>2</sub> in 0.5 M KHCO<sub>3</sub> while adding a concentration of gaseous CO<sub>2</sub> of MFC and MFC with a zero-gap anode can decrease overall conversion.
2. The MFC with a zero-gap anode configuration which is designed to overcome the mass transfer limitation of MEAFC configuration and ohmic loss polarization of MFC configuration. Therefore, this design configuration provides high values of the product selectivity, FE, and EE of CO<sub>2</sub> RR.
3. Applied current density not only directly affects  $X_{CO_2}$  but also directly affects product selectivity, FE, and EE of CO<sub>2</sub> RR of the activation of applied bias would excite electrons to reduce CO<sub>2</sub> on the cathode surface. However, the excess applied current densities cause product selectivity, FE, and EE of CO<sub>2</sub> RR tended to decrease due to the competition of HER.

4. The optimum PEC cell length should be concerned, although longer cells can provide the increase in  $X_{CO_2}$  from a larger surface area for electrochemical reactions. In contrast, when the PEC cell length is too long, it can cause a diminished average  $CO_2$  concentration in the cell which results in continuously decreasing product selectivity, FE, and EE of  $CO_2$  RR.
5. Similarly, the optimum width of the fluid channels should be concerned. The wider fluid channels can improve  $X_{CO_2}$  from a longer residence time for electrochemical reactions. Regarding the product selectivity, FE, and EE of  $CO_2$  RR tends to decrease when using wider fluid channels since the loss of ohmic from the product accumulation on the electrode surface.

## 5.2 Recommendations for the future work

1. Investigate the effect of the pH of electrolyte solution to estimate the optimal electrochemical environment for  $CO_2$  RR to CO and  $HCOO^-$ .
2. Investigate and simulate another type of ion-exchange membrane for the PEC cell model, such as an anion exchange membrane (AEM) and bipolar exchange membrane, to determine the best performance of PEC cell for  $CO_2$  RR to CO and  $HCOO^-$ .

## APPENDIX

### Appendix A: Calculation of diffusion coefficient of multicomponent

The diffusion coefficient of the multicomponent can be determined using the correlation of Fuller, Schettler, and Giddings, as shown in Eq (13) [69].

$$D_{ij} = \frac{10^{-3} T^{1.75} \left( \frac{1}{M_i} + \frac{1}{M_j} \right)^{1/2}}{p (v_i^{1/3} + v_j^{1/3})} \quad \text{Eq. (13)}$$

where  $D_{ij}$  is multicomponent diffusion coefficient ( $\text{cm}^2 \cdot \text{s}^{-1}$ )

$T$  is temperature (K)

$p$  is the pressure (atm)

$v_i$  is the diffusion volume for molecule  $i$

$M_i$  is molecular weight of gas  $i$  ( $\text{g} \cdot \text{mol}^{-1}$ )

**Table 14.** The diffusion volume for molecule  $i$

Parameters of gas $i$	Symbol	Value	Unit	Ref.
Molecular weight of $\text{CO}_2$	$M_{\text{CO}_2}$	44.01	$\text{g} \cdot \text{mol}^{-1}$	[102]
Molecular weight of $\text{CO}$	$M_{\text{CO}}$	28.01	$\text{g} \cdot \text{mol}^{-1}$	
Molecular weight of $\text{H}_2$	$M_{\text{H}_2}$	2.02	$\text{g} \cdot \text{mol}^{-1}$	
Molecular weight of $\text{N}_2$	$M_{\text{N}_2}$	28.01	$\text{g} \cdot \text{mol}^{-1}$	
Molecular weight of $\text{O}_2$	$M_{\text{O}_2}$	32.00	$\text{g} \cdot \text{mol}^{-1}$	
Molecular weight of $\text{H}_2\text{O}$	$M_{\text{H}_2\text{O}}$	18.02	$\text{g} \cdot \text{mol}^{-1}$	
Diffusion volume of $\text{CO}_2$	$v_{\text{CO}_2}$	26.9	$\text{cm}^3 \cdot \text{mol}^{-1}$	[69]
Diffusion volume of $\text{CO}$	$v_{\text{CO}}$	18.9	$\text{cm}^3 \cdot \text{mol}^{-1}$	
Diffusion volume of $\text{H}_2$	$v_{\text{H}_2}$	6.12	$\text{cm}^3 \cdot \text{mol}^{-1}$	
Diffusion volume of $\text{N}_2$	$v_{\text{N}_2}$	17.9	$\text{cm}^3 \cdot \text{mol}^{-1}$	
Diffusion volume of $\text{O}_2$	$v_{\text{O}_2}$	16.6	$\text{cm}^3 \cdot \text{mol}^{-1}$	
Diffusion volume of $\text{H}_2\text{O}$	$v_{\text{H}_2\text{O}}$	12.7	$\text{cm}^3 \cdot \text{mol}^{-1}$	

The multicomponent diffusion coefficients,  $D_{ij}$  are defined as using Eq. (13).

$$D_{CO_2CO} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{44.01} + \frac{1}{28.01}\right)^{1/2}}{(26.9^{1/3} + 18.9^{1/3})} = 9.14 \times 10^{-5} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{CO_2H_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{44.01} + \frac{1}{2.02}\right)^{1/2}}{(26.9^{1/3} + 6.12^{1/3})} = 3.20 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{CO_2N_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{44.01} + \frac{1}{28.01}\right)^{1/2}}{(26.9^{1/3} + 17.9^{1/3})} = 9.21 \times 10^{-5} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{CO_2O_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{44.01} + \frac{1}{32.00}\right)^{1/2}}{(26.9^{1/3} + 16.6^{1/3})} = 1.12 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{CO_2H_2O} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{44.01} + \frac{1}{18.02}\right)^{1/2}}{(26.9^{1/3} + 12.7^{1/3})} = 8.96 \times 10^{-5} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{COH_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{2.02}\right)^{1/2}}{(18.9^{1/3} + 6.12^{1/3})} = 3.47 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{CON_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{28.01}\right)^{1/2}}{(18.9^{1/3} + 17.9^{1/3})} = 1.08 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{COO_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{32.00}\right)^{1/2}}{(18.9^{1/3} + 16.6^{1/3})} = 1.06 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{COH_2O} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{18.02}\right)^{1/2}}{(18.9^{1/3} + 12.7^{1/3})} = 1.29 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{N_2H_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{2.02}\right)^{1/2}}{(17.9^{1/3} + 6.12^{1/3})} = 3.51 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{N_2O_2} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{32.00}\right)^{1/2}}{(17.9^{1/3} + 16.6^{1/3})} = 1.07 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{N_2H_2O} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{28.01} + \frac{1}{18.02}\right)^{1/2}}{(17.9^{1/3} + 12.7^{1/3})} = 3.82 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{H_2H_2O} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{2.02} + \frac{1}{18.02}\right)^{1/2}}{(6.12^{1/3} + 12.7^{1/3})} = 3.82 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

$$D_{O_2H_2O} = \frac{10^{-3}(298.15^{1.75})\left(\frac{1}{32.00} + \frac{1}{18.02}\right)^{1/2}}{\left(16.6^{1/3} + 12.7^{1/3}\right)} = 1.29 \times 10^{-4} \text{ m}^2 \cdot \text{s}^{-1}$$

### Appendix B: Calculation of permeability of GDE

The permeability of GDE is the average permeability of a porous medium consisting of a catalyst layer (CL) and a diffusion layer (GDL). The predicted model of Tomadakis-Sotirchos is used to identify the permeability of GDE as following Eq. (41) [69].

$$\mathcal{K} = \frac{\varepsilon}{8 \ln^2 \varepsilon} \frac{(\varepsilon - \varepsilon_p)^{\alpha+2} r_f^2}{(1 - \varepsilon_p)^\alpha [(\alpha+1)(\varepsilon - \varepsilon_p)]^2} \quad \text{Eq. (41)}$$

where  $\mathcal{K}$  is the average permeability of the porous medium

$\varepsilon$  is the average porosity

$\varepsilon_p$  is the percolation threshold porosity ( $\varepsilon_p = 0.11$ )

$\alpha$  is the fitting parameter for trough-plan diffusion ( $\alpha = 0.785$ )

$r_f$  is the carbon fiber radius ( $r_f = 4.6 \times 10^{-6}$  m)

Besides, the average porosity of GDE can be defined following Eq. (42).

$$\varepsilon = \frac{\varepsilon_{cl} + \varepsilon_{gdl}}{2} \quad \text{Eq. (42)}$$

where  $\varepsilon_{cl}$  is the porosity of catalyst layer ( $\varepsilon_{cl} = 0.4$ )

$\varepsilon_{gdl}$  is the porosity of gas diffusion layer ( $\varepsilon_{gdl} = 0.663$ )

Therefore, the parameter values are substituted to specify the average permeability of the porous medium as follows.

$$\varepsilon = \frac{0.4 + 0.663}{2} = 0.5315$$

$$\mathcal{K} = \frac{0.5315}{8 \ln^2(0.5315)} \frac{(0.5315 - 0.11)^{0.785+2} (4.6 \times 10^{-6} \text{ m})^2}{(1 - 0.11)^{0.785} [(1 - 0.11)(0.5315 - 0.11)]^2}$$

$$\mathcal{K} = 2.47 \times 10^{-12} \text{ m}^2$$

### Appendix C: Calculation of fluid velocity

The flow regime of fluid is assumed to be laminar flow which depends on the range of Reynold's number ( $Re$ ). The correlation between the inlet of fluid velocity and  $Re$  is identified as following Eq. (21).

$$u = \frac{\mu Re}{\rho L} \quad \text{Eq. (21)}$$

where  $u$  is fluid velocity ( $m \cdot s^{-1}$ )

$\mu$  is dynamic fluid viscosity ( $kg \cdot m^{-1} \cdot s^{-1}$ )

$Re$  is Reynold numbers ( $Re < 2000$ )

$L$  is characteristic length (m)

$\rho$  is fluid density ( $kg \cdot m^{-3}$ )

However, the characteristic length,  $L$  replies to the geometry of reactors. The fluid flow channels of the 2-dimensional model of PEC are designed to be rectangular ducts so  $L$  can be defined from the hydraulic diameter,  $D_h$  as Eq. (43).

$$D_h = \frac{4ab}{2(a+b)} = \frac{2ab}{a+b} \quad \text{Eq. (43)}$$

where  $a$  is channel width and is  $b$  channel height (m)

For electrolyte channels, the hydraulic diameter,  $D_h$  defined as:

$$D_{h,elec} = \frac{2(0.0015 \text{ m} \times 0.015 \text{ m})}{0.0015 \text{ m} + 0.015 \text{ m}} = 0.0027 \text{ m}$$

The inlet of electrolyte velocity when  $Re < 2000$ :

$$u_{elec} = \frac{\mu_l Re}{\rho_l D_{h,elec}} \quad \text{Eq. (44)}$$

$$u_{elec} = \frac{(1.07 \times 10^{-3} \text{ kg}\cdot\text{m}^{-1}\text{s}^{-1})(2000)}{(1030 \text{ kg}\cdot\text{m}^{-3})(0.0027 \text{ m})} = 0.8 \text{ m}\cdot\text{s}^{-1}$$

Also, the inlet of electrolyte velocity,  $u_{elec}$  is set to less than  $0.8 \text{ m}\cdot\text{s}^{-1}$  to control the laminar flow regime of the electrolyte.

For gas channel, the hydraulic diameter,  $D_h$  defined as:

$$D_{h,gas} = \frac{2(0.0015 \text{ m} \times 0.015 \text{ m})}{0.0015 \text{ m} + 0.015 \text{ m}} = 0.0027 \text{ m}$$

The inlet of gas velocity when  $Re < 2000$ :

$$u_{gas} = \frac{\mu_g Re}{\rho_g D_{h,gas}} \quad \text{Eq. (45)}$$

$$u_{gas} = \frac{(1.665 \times 10^{-5} \text{ kg}\cdot\text{m}^{-1}\text{s}^{-1})(2000)}{(1.410 \text{ kg}\cdot\text{m}^{-3})(0.0027 \text{ m})} = 8.7 \text{ m}\cdot\text{s}^{-1}$$

Also, the inlet of electrolyte velocity,  $u_{gas}$  is set to less than  $8.7 \text{ m}\cdot\text{s}^{-1}$  to control the laminar flow regime of the electrolyte.

#### Appendix D: Calculation initial concentration of dissolved species

In order to simulate the electrochemical reduction reaction of CO<sub>2</sub> to desired products at the interface of electrolyte/electrode, initial concentrations of dissolved species are required. The solubility of gaseous CO<sub>2</sub> in the aqueous electrolyte solution are necessary to study because concentration of salt of electrolyte can affect to mass transfer in CO<sub>2</sub> RR. The solubility of CO<sub>2</sub> in salt solution can apply the Schump relation which describes effect of moderate to high salt concentration on gas solubility as Eq. (46).

$$\log\left(\frac{c_{G,0}}{c_G}\right) = \sum(h_i + h_G)c_i \quad \text{Eq. (46)}$$

where  $c_{G,0}$  is the concentration dissolved gas in pure water

( $c_{G,0}$  at 298 K is 33.95 mol·m<sup>-3</sup>)

$c_G$  is the concentration dissolved gas in salt solution (mol·m<sup>-3</sup>)

$c_i$  is the concentration of ion or dissolved species

( $c_i$  of 0.5 M KHCO<sub>3</sub> is 500 mol·m<sup>-3</sup>)

$h_i$  is the ion specific parameter (m<sup>3</sup>·mol<sup>-1</sup>)

$h_G$  is the gas specific parameter (m<sup>3</sup>·mol<sup>-1</sup>)

The specific parameters of gas ( $h_G$ ) depends on temperature, therefore,  $h_G$  can be defined by following Eq. (47).

$$h_G = h_{G,0} + h_T(T - 298.15 \text{ K}) \quad \text{Eq. (47)}$$

where  $h_{G,0}$  is the gas specific parameter at reference temperature (m<sup>3</sup>·mol<sup>-1</sup>)

$h_T$  is the gas specific parameter for the temperature effect (m<sup>3</sup>·mol<sup>-1</sup>·K<sup>-1</sup>)

$T$  is temperature (K)

**Table 15.** The specific parameters for calculation of the solubility of gases in aqueous electrolyte [44].

Parameters	Dissolved species	Value	Unit
$h_{G,0}$	CO <sub>2</sub>	-1.83 × 10 <sup>-5</sup>	m <sup>3</sup> •mol <sup>-1</sup>
$h_T$ at 273-313 K		-3.38 × 10 <sup>-7</sup>	m <sup>3</sup> •mol <sup>-1</sup> •K <sup>-1</sup>
$h_i$	CO <sub>3</sub> <sup>2-</sup>	14.23 × 10 <sup>-4</sup>	m <sup>3</sup> •mol <sup>-1</sup>
	HCO <sub>3</sub> <sup>-</sup>	13.72 × 10 <sup>-5</sup>	m <sup>3</sup> •mol <sup>-1</sup>
	H <sup>+</sup>	0.00	m <sup>3</sup> •mol <sup>-1</sup>
	OH <sup>-</sup>	8.39 × 10 <sup>-5</sup>	m <sup>3</sup> •mol <sup>-1</sup>
	K <sup>+</sup>	9.59 × 10 <sup>-5</sup>	m <sup>3</sup> •mol <sup>-1</sup>

For this system, the solubility of CO<sub>2</sub> at 298.15 K in 0.5 M KHCO<sub>3</sub>:

$$h_G = -1.83 \times 10^{-5} - 3.38 \times 10^{-7} (298.15 - 298.15) = -1.83 \times 10^{-5} \text{ m}^3 \cdot \text{mol}^{-1}$$

$$\begin{aligned} \log \left( \frac{c_{G,0}}{c_G} \right) &= (500 \text{ mol} \cdot \text{m}^{-3}) (13.72 \times 10^{-5} - 1.83 \times 10^{-5} \text{ m}^3 \cdot \text{mol}^{-1}) && (\text{HCO}_3^{1-}) \\ &+ (500 \text{ mol} \cdot \text{m}^{-3}) (9.59 \times 10^{-5} - 1.83 \times 10^{-5} \text{ m}^3 \cdot \text{mol}^{-1}) && (\text{K}^+) \\ &= 0.0983 \end{aligned}$$

At 298.15 K, concentration of dissolved CO<sub>2</sub> in pure water is 33.95 mol•m<sup>-3</sup>, so concentration of CO<sub>2</sub> in 0.5 M KHCO<sub>3</sub> is:

$$\log \left( \frac{33.95}{c_G} \right) = 0.0983, \quad c_G = 27.08 \text{ mol} \cdot \text{m}^{-3}$$

The value of  $c_G$  is substituted as concentration of dissolved CO<sub>2</sub> in the 0.5 M KHCO<sub>3</sub> at 25 °C, [CO<sub>2(diss)</sub>]. Besides, the initial conditions for electrolyte without CO<sub>2</sub> saturated, the concentration of dissolved CO<sub>2</sub> is assumed to be 1 mol•m<sup>-3</sup>. The other dissolved species or ionic species in the electrolyte can specify by using a concentration of dissolved CO<sub>2</sub> in the electrolyte solution and equilibrium constants for the absorption of CO<sub>2</sub> in 0.5 M KHCO<sub>3</sub> at 25 °C.

To obtain the initial conditions of dissolved species, the equilibrium constants which performed in neutral to alkaline solution in reactions (23), (26) and (27) are rearranged as Eq. (48) to (50).

$$K_{3,6} = \frac{k_{23f}}{k_{23b}} = \frac{[H^+][HCO_3^-]}{[CO_{2(L)}]} = 4.60 \times 10^{-4} \text{ mol} \cdot \text{m}^{-3} \quad \text{Eq. (48)}$$

$$K_{3,9} = \frac{k_{26f}}{k_{26b}} = \frac{[CO_3^{2-}]}{[HCO_3^-][OH^-]} = 4.69 \text{ m}^3 \cdot \text{mol}^{-1} \quad \text{Eq. (49)}$$

$$K_w = [H^+][OH^-] = 1.00 \times 10^{-14} \text{ m}^6 \cdot \text{mol}^{-2} \quad \text{Eq. (50)}$$

Rearrange equations as:

$$[H^+][HCO_3^-] = K_{3,6}[CO_{2(L)}] \quad \text{Eq. (48)}$$

$$[CO_3^{2-}] = K_{3,9}[HCO_3^-][OH^-] \quad \text{Eq. (49)}$$

$$K_w [H^+][OH^-] = 1 \quad \text{Eq. (50)}$$

In addition, equations from  $CO_2$  balance and electroneutrality condition are applied to solve the initial condition as following Eq (51) to (53).

$$[CO_{2(diss)}] + [HCO_3^-] = [CO_{2(L)}] + [HCO_3^-] + [CO_3^{2-}] \quad \text{Eq. (51)}$$

$$[K^+] + [H^+] = [OH^-] + [HCO_3^-] + 2[CO_3^{2-}] \quad \text{Eq. (52)}$$

$$[K^+] + \frac{K_w}{[OH^-]} = [OH^-] + K_{3,6}[CO_{2(L)}][OH^-] + 2K_{3,6}K_{3,9}[CO_{2(L)}][OH^-]^2 \quad \text{Eq. (53)}$$

The electroneutrality condition is provided in Eq. (53) is applied for iteration method for solving  $[OH^-]$ . The initial concentrations of dissolved species are substituted in physics modeling of PEC  $CO_2$  RR as shown in table 13.

### Appendix E: The results data for physics model validation and RMSE calculation

The FE of CO<sub>2</sub> conversion to HCOO<sup>-</sup> as a function of the cell voltage was compared with the experimental results of I. E. Irem et al [84] as shown in table 16. The MFC configuration with assembling of Sn based GDE cathode as a working-electrode and dimensional stable anode (DSA) as a counter-electrode simulated full cell of electrochemical CO<sub>2</sub> RR to HCOO<sup>-</sup> under controlled operating conditions. Similarly operating conditions such as operating temperature and pressure at ambient conditions, pH range of electrolyte in alkaline conditions, and equality of gas to liquid feeding (G/L: 1) were set to achieve the optimum performance of the physics model. The supplied electric of CO<sub>2</sub> conversion to HCOO<sup>-</sup> for experimental quantification was as 4 C•ml<sup>-1</sup> of catholyte. Calculation FE of HCOO<sup>-</sup> was used as the performance indicator following Eq. (4).

$$\begin{aligned} \text{FE}(\%) &= \frac{e_{\text{output}}}{e_{\text{input}}} \times 100\% \\ &= \frac{n \text{ (mol)} \times y}{\frac{Q \text{ (Coulomb)}}{F \text{ (Coulomb/mol)}}} \times 100\% \end{aligned} \quad \text{Eq. (4)}$$

where  $n$  = the number of moles of the desired product

$y$  = the number of electrons needed to convert CO<sub>2</sub> into the desired product

$Q$  = the calculated electric charge (Coulomb)

$F$  = the Faraday constant (96485 Coulombs/mols of desired product)

Obviously, the root mean square error (RMSE) is calculated to represent the discrepancy of FE<sub>HCOO<sup>-</sup></sub> between the experiment and physics model as a function of cell voltage 1.5 to 3.0 V from following Eq. (54).

$$\text{RMSE} = \sqrt{\frac{1}{F} \sum_{i=1}^F (y_i - \hat{y}_i)^2} \quad \text{Eq. (54)}$$

where RMSE is root mean square error

$F$  is the number of data point

$y_i$  is the actual data or results data from experiment

$\hat{y}_i$  is the predicted value or results data from physics model

**Table 16.** The results data of CO<sub>2</sub> conversion to HCOO<sup>-</sup> as a function of the cell voltage for physics model validation. Volumetric flow rate: 10 ml•min<sup>-1</sup>.

E <sub>cell</sub>   (V)	Physics model						FE <sub>HCOO<sup>-</sup></sub> from experiment (%)	Root means square error (RMSE)
	Current density (mA•cm <sup>-2</sup> )	HCOO <sup>-</sup> concentration		HCOO <sup>-</sup> rate (mmol•m <sup>-2</sup> •s <sup>-1</sup> )	FE <sub>HCOO<sup>-</sup></sub> (%)			
		(mmol•m <sup>-3</sup> )	(mg•L <sup>-1</sup> )

### Appendix F: The results data for study variables affecting PEC CO<sub>2</sub> RR.

The performance indicators are used to define the effect of variables affecting PEC CO<sub>2</sub> RR, calculation of CO<sub>2</sub> conversion ( $X_{CO_2}$ ), selectivity (S), and energy efficiency following Eq. (2), (3), and (5).

$$X_{CO_2} = \frac{F_{CO_2,0} - F_{CO_2}}{F_{CO_2,0}} \quad \text{Eq. (2)}$$

where  $F_{CO_2,0}$  is the initial molar flow rate of CO<sub>2</sub> (mol/s)

$F_{CO_2}$  is the final molar flow rate of CO<sub>2</sub> (mol/s)

$$S = \frac{\text{Moles formed of interested product}}{\text{Moles formed of overall products}} \quad \text{Eq. (3)}$$

$$\begin{aligned} \text{EE(\%)} &= \frac{\text{Productivity (mol s}^{-1}\text{)} \cdot \Delta H_{\text{comb}}^{\circ} (\text{J mol}^{-1})}{I_{\text{cell}} (\text{A}) \cdot E_{\text{cell}} (\text{V})} \times 100 \\ &= \text{FE(\%)} \times \frac{E_{\text{therm}} (\text{V})}{E_{\text{cell}} (\text{V})} \quad \text{Eq. (5)} \end{aligned}$$

where  $\Delta H_{\text{comb}}^{\circ}$  is the combustion energy under standard conditions

$E_{\text{therm}}$  is the thermoneutral voltage

**Table 17.** The combustion energy and thermoneutral voltage of various products at standard conditions [103].
